This revival of interest is shown in the extraordinary number of articles, monographs, and special treatises on leprosy which have appeared, the most recent, and, in some respects, the most valuable of which is the work of Dr. Thin, which forms the subject of this notice.

In this little book of two hundred and eighty pages the author has endeavored to systematize and present in a condensed form the essential facts of our knowledge of this dreadful and mysterious malady. This information has been chiefly collated from the larger classical treatises on leprosy, and with it have been incorporated many new and important facts bearing upon the etiology and contagiousness of the disease which have appeared in recent periodical literature.

The admirable account of the history and geographical distribution of leprosy with which the book opens is most interesting and instructive. The remarkable development and increase of leprosy in Europe, its no less remarkable decline, the comparative immunity of the United States, the conditions which favor its propagation and spread are problems yet unsolved and full of interest.

Our knowledge of the symptomatology, pathology, etiology, and treatment of the disease is summarized in a clear, concise, and complete manner. The chapter on pathology contains a full account of the bacillus lepræ, its microscopical appearance, growth, and other characteristics, its habitat in the tissues and its relation to the pathological changes peculiar to leprosy. The evidence of the contagiousness of the disease is not based solely upon the demonstration of its parasitic nature, but is reinforced by numerous and most convincing proofs. A large number of authentic cases are cited, which show in the most indubitable manner the communicability of the disease to healthy persons who have been brought in contact with lepers. The hereditary hypothesis the author regards as untenable and not to be reconciled with the recognition of a micro-organism as the pathogenetic agent. In discussing the treatment of leprosy the majority of agents and methods which have been employed are mentioned only

to be condemned. Especial prominence is given to the two remedies, gurjun oil and chaulmoogra oil, which at the present time hold the first place in professional favor. The results of all treatment are confessed to be deplorably unsatisfactory.

The work is enriched by three autotype illustrations, representing the tubercular and nerve types of leprosy, and photomicrographs of the bacilli lepræ.

Evidences of the Communicability of Consumption. By S. A. Heron, M.D. Glasgow.

The author has studied the bacteriological relationship in tuberculosis and regards everything existing as cause and effect.

The Johns Hopkins Hospital Reports. Report of Pathology of Amœbic Dysentery. By William T. Councilman, M.D., and Henri A. Lofleur, M.D.

A very careful and thorough investigation, giving as a cause the amœbœ dysentorie, and recognizing a new disease by the above title.

Ptomaïnes, Leucomaïnes, and Bacterial Proteids; or, The Chemical Factors in the Causation of Disease. By Victor C. Vaughan, Ph.D., M.D., and Frederick S. Novy, Sc.D., M.D.

This little work is a very welcome addition to our present knowledge of the germs and their direct relation to the causation of disease. The question of immunity, also mentioned, is lightly touched upon.

Die Untersuchung des Auswurfs auf Tuberkelbacillen. Von Dr. Eugen Czaplewski.

This is a very elaborate and thorough work, giving all the methods employed for staining the tubercle bacillus. Although too lengthy for the average practitioner it is complete in all its details.

The Pathology and Treatment of Glaucoma. By Priestley Smith, Ophthalmic Surgeon and Clinical Lecturer on Diseases of the Eye, Queen's Hospital, Birmingham. Author of the "Jacksonian Prize-Essay on Glaucoma," Royal College of Surgeons, 1879. With Sixty-four Illustrations by the Author, and twelve Photo zincographs. Pp. 186. London: J. & A. Churchill. 1891.

This octavo volume is a *brochure* of the three revised Erasmus Wilson Lectures, which were delivered at the Royal College of Surgeons of England, in March, 1891. It treats of the causes of glaucoma and its attendant symptoms in a masterly way. The word signifying this disease first referred to the color of the pupil, which became green-blue instead of remaining black. But as this green-bluish background of the pupil is a mere concomitant symptom; and as intra-ocular pressure is now recognized as the chief determining feature, if not the cause, of the disease, glaucoma is no longer a suitable name for it. Hardness of the eyeball received only casual notice at the hands of oculists fifty years ago; and it was not until 1830, twenty years before Helmholtz brought forward the ophthalmoscope as a physical instrument, that Mackenzie, still unable to perceive the fundus of the eye, first attempted relief of the tension by scleral puncture. The introduction of iridectomy by von Graefe was the result of his conviction that increased hardness of the eyeball and cupping of the disk were the direct causes of the malady, and these he discovered by aid of the ophthalmoscope. The author ably reviews the attempts at measuring ocular tension, and elaborates his own simple tonometric instrument. This apparatus consists of two glass reservoirs, open at the top, which are hung against an upright. A siphon-tube is connected with each, partly rubber and partly glass, which is carried along a graduated horizontal bar; two rubber tubes descend from the horizontal bar, to which are attached two hollow needles, one of these carries injecting fluid to the anterior chamber, the other to the vitreous chamber of an eye placed on a tripod. The known factors are the contents of each reservoir, the cubical contents of each tube, and the pressure of the fluid, which, when water was used, was 30 c.c., and when mercury, was 25 c.c. Each of these representing about the normal pressure.

By this apparatus, carmine and Prussian blue, or hydrocyanic acid, or persulphate of iron in solution, is injected first into the aqueous, then into the vitreous, then simultaneously into both humors, with the results that the molecular pressure of each humor and the course of the fluids are determined. It may here be noted that the first experimenter upon the eye with similar physical apparatus was Max Kries, about fifteen years ago; his idea being that glaucoma and intra-ocular increase of tension were dependent upon the movability of the spaces at the heel of the iris to act as a filter to the fluid contents of the eyeball.

The causes of glaucoma may be summarized as follows: They are all alike in that they lead to compression of the filtration-angle, and this is the moment when begins the actual glaucoma process. The words of the author are so terse and significant that they are here reproduced: "The escape of fluid is retarded and the intra-ocular pressure rises; the increasing pressure hinders the flow of blood through the choroidal veins, and augments the swelling of the ciliary processes; this, in turn, increases the compression of the filtration-angle. The fluid which still exudes from the turgid ciliary body is albuminous and less diffusible than the normal secretion; it tends to accumulate behind the lens, and this latter, being pressed forward, intensifies the mischief. Thus cause and effect react upon each other in a vicious circle."

Under the head of treatment nothing new is offered. The plan is emphasized of adopting such measures as tend to reduce the increased tension. Eserine is the chief medicinal agent, and atropine is to be avoided, while the value of cocaine is noted on account of its ability to contract the ciliary blood-vessels and diminish the sensibility of the ciliary nerves. Of operative procedures iridectomy must take precedence, while sclerotomy must be regarded as supplemental to it. Von Graefe, though the author of iridectomy for the relief of glaucoma, was unable to explain its *rationale* as we know it to-day.

An appendix is added to the lectures, giving, first, statistics of primary glaucoma in relation to age, sex, and type; and, second, statistics of the weight, volume, and specific gravity of the crystalline lens at different times of life, the perusal of which will afford unusual interest. A short and practical chapter on the methods of preserving and draining ophthalmic specimens closes the *brochure*.

This little work will repay the reader of general medical literature. The genuine and somewhat novel character of the experiments in tonometry; the balance of guarded opinion given to every step of argument; the terse and choice English diction make this book a gem to every student. Author and publishers have made choice selections in illustration.

Artesian Wells.—The drillers engaged in sinking a well for the Natatorium at Fort Worth, Tex., struck a flow of water which excels that of any artesian well known. The flow is 600 gallons per minute, and is as clear as crystal. The well is 1,052 feet deep, with a 10-inch bore at the top, tapering to five inches at the bottom. Fort Worth can boast of the largest flowing well in existence, the largest hitherto known being at Bourne, Lincolnshire, England, which discharges 500,000 gallons daily. At Aire, in the province of Artois, France, from which province is derived the name of artesian wells, there is a well from which the water has continued to flow for more than a century, and at the old Carthusian convent at Lillers there is another which dates back from the twelfth century.—*Sanitary News.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 4, 1892.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Practicable and Impracticable Methods for Preventing the Spread of Phthisis Pulmonalis.—DR. J. WEST ROOSEVELT read the paper, which was a continuation of the discussion of the same subject opened at the previous meeting. While admitting that without the bacillus there could be no tuberculosis, yet it should not be forgotten that not all practicable measures for the prevention of the spread of the disease must have for their aim the destruction of the bacillus. The paper, however, was limited chiefly to a consideration of the practicable and the impracticable measures which were based on the infectious nature of the disease. It seemed to the author that the medical profession, or individual members of that profession, were not altogether exempt from the charge of having suggested some preventive measures which were worse than impracticable; they were absurd and preposterous. In some of the cases the absurdity of the suggestions depended alone upon their utter impracticability; in others, also, upon their being opposed to reason. No measures whatever would prove practical until the public had learned the necessity for their adoption through selfish motives, for it was through selfish motives that people usually were led to give themselves much or little trouble about anything.

It was known that the tubercle bacilli entered the human body usually through the air-passages and the alimentary tract, sometimes through the broken skin; it was known that the soil suitable for their development was the body of warm-blooded animals; it was further known that they could retain their vitality a long time in a warm medium, and could be excited to renewed activity by being transported into the lungs, or other tissues. What was not known, however, was from what the tubercle bacilli originated before they took on their virulent character. It was not improbable that there were countless millions of forms which remained harmless until special conditions arose when they became virulent tubercle bacilli. In other words, it was not impossible but what the tubercle-producing bacilli were descendants of countless millions of perfectly harmless bacteria, and acquired their virulent properties through peculiar conditions. If this were so, who could say that tubercle bacilli might not develop outside the animal body. Yet this did not argue against our destroying, as far as possible, those known to exist and to be disease producing.

It was useless to advocate any measure which aimed at absolutely preventing the spread of the tubercle bacillus. To accomplish that, it would be necessary that all persons known to be suffering from tuberculosis should be segregated, which would mean in the United States several hundred thousand. It would also mean the temporary segregation of all persons suspected of having tuberculosis, which would run the number up into several millions. It would also necessitate the destruction of all cattle and animals known to be tuberculous, and the disinfection of the carcasses, the disinfection of barns, etc., and these the author seemed to think would be possible. It would also mean that all milk, water, and food should be sterilized, that is, overcooked. Somebody had made the suggestion in good earnest that every house in which a tuberculous patient had lived should be destroyed by fire. Even if all these suggestions were put into practice it would require two or three generations before practical results would follow.

It was bad to suggest disinfecting measures which really did not disinfect, as their application gave the people a false sense of security. Methods had been suggested for disinfection with which, the author thought, common sense had had nothing to do. He so characterized sulphur fumigation, which was still believed in by the laity and received countenance from some physicians. It had proven of some benefit, however, in compelling the people subsequently to thoroughly ventilate their rooms. The best disinfectants were circulation of air and washing with soap and water. It might well be questioned whether the chemical disinfectants had not proven more hurtful than helpful to humanity. It was also a question whether, on the whole, antiseptics as applied in medicine had not done more harm than good. Aseptic methods, even though not possessing all the qualities of antiseptics, did not at least poison patients. Antiseptics, he said, had often had a peculiar effect upon the brain of the men employing them. The portion of the brain affected was especially that which was concerned in the perception of logic.

DR. ROOSEVELT held up to ridicule the idea that a condition of sepsis could be induced by the spray of carbolic acid which should kill the germs floating in the air, also that germs of disease could be destroyed by rectal injections of gas, the inhalation of hot air, or swallowing a sufficient quantity of an antiseptic solution. Nor would much be accomplished by promulgating any scheme which in its main feature dealt with disinfection by the individual.

Passing to the consideration of the most frequent sources of infection, the author said that from inhalation of dried sputum in the air had received attention at the last meeting, and he would only speak of the danger of ingestion of tuberculous meat and milk. The flesh of cows and fowls was often tuberculous, and from this source was one of the greatest dangers of infection. The author expressed the opinion that there was really no such thing as a localized tuberculosis. That where there was apparently a local tuberculosis, shown for instance in enlarged glands, the tissues in any part of the body might contain the tubercle bacilli although in a latent state, and it was unsafe to use the animal for food. It was his opinion that no amount of money would justify letting an animal live, even when suspected of tuberculosis.

The danger of tubercle bacilli getting into the respiratory passages, and especially of reaching the lungs, was a great deal less than the danger of their entering the alimentary canal. It was not seldom that in sweeping rooms with closed doors and windows, it was done in a manner to stir up a great deal of dust laden with the bacilli of tuberculosis, yet it was under such favorable conditions that the cases of known infection by this method had taken place. There was much more likelihood of getting an overdose of the virulent germs through the alimentary tract either by the ingestion of meat, milk, or in children by putting articles of every nature into their mouths, no matter where they may have lain. Whatever plan might be adopted by the Board of Health, by medical societies, etc., for preventing the spread of tuberculous phthisis, none would prove effective without constant reiteration from year to year.

Illogical Logic.—DR. C. E. QUIMBY said he must disagree entirely with Dr. Roosevelt. The paper seemed to be based upon this proposition: that phthisis depended upon tuberculosis; that tuberculosis depended upon a bacillus; that therefore without the bacillus we would have no phthisis; hence, we must kill the bacillus. The speaker regarded that logic as fallacious. It was fallacious in that sight had apparently been lost of the fact that pulmonary tuberculosis did not develop without a lung. Practically, therefore, the one thing which phthisis depended upon was a lung. It seemed to him that Dr. Roosevelt and others had made the mistake of looking at their argument through a pin-hole with the eye close to the hole; if they would only remove the eye a little ways from the hole the argument wouldn't look half so large.

The author himself had shown the practical impossi-

bility of getting rid of all tubercle bacilli, and had not stopped there, but had suggested the possibility even of countless millions outside the animal economy which might under suitable conditions take on a virulent character. The idea that the spread of tuberculosis could be prevented by destruction of all the bacilli of this disease was expressed with about as much thought as the homœopathists manifested when they asserted that a teaspoonful of a thirtieth dilution had curative effects. The speaker had by computation shown that one drop of a fluid diluted to the thirtieth degree would require more water than equalled the earth's bulk. Bacilli had their distinct purpose in the world, and even if it were for the interest of man to destroy them it was probable the task would not have been accomplished before the destruction of the planet we lived on. But bacilli did not grow in lungs under certain conditions, and the speaker thought it much wiser to bring about these conditions than to attempt to destroy the wicked germs. He believed the temperance people were doing more to prevent the spread of phthisis than doctors, or societies, or health boards would do by trying to destroy bacilli or prevent their distribution. The germs had an easy time when they got to the lungs of one addicted to spirituous liquors. He heartily agreed with Dr. Roosevelt in advocating fresh air and ventilation of homes. One who had the so-called fibroid diathesis was not likely to be affected with tuberculosis, and he recommended the bringing about of this state of the system by manner of living and choice of companions.

Dr. Roosevelt here expressed the view that the remarks of the gentleman were not germane to the subject. It was about as appropriate to speak about eradicating the bacilli of tuberculosis from the face of the earth as to suggest by way of preventing the spread of phthisis that the constitutions of all men be made to take on the fibroid diathesis.

Dr. F. W. Jackson thought that something could be done to limit the spread of pulmonary tuberculosis. The thing of first importance was to impress upon the public that it was an infectious disease. Tenement-house people should be taught that the disease could be conveyed from one person to another, and what were the most likely means of transportation. The same thing could be impressed upon persons seen in private practice. He knew of no drug which was a blood antiseptic. The methods of prevention which he mentioned were disinfection of sputum, inhalation of fresh air, cleanliness, avoidance of tuberculous milk and meat. Laws of hygiene should in general be observed.

Dr. LeFevre said it was only since the cause of pulmonary phthisis in the tubercle bacillus had been recognized that we had received any hope of checking the spread of the disease. In teaching the people that it was contagious or infectious, they should at the same time be taught in just how far, in order that a panic might not be created, and an injury be done both the sick and well. In practical measures, he did not think we could act on the basis of inducing tuberculous patients in any great degree to take steps against sowing the seeds of the disease. On the whole, prevention resolved itself largely into a question of good health and hygiene.

Dr. Agramonte spoke of the much greater number of disease germs to the cubic metre of air in cities than in the country, over the sea, and at high altitudes. The dust of our streets was impregnated with them. This settled in our houses, even where the doors and windows were kept closed. Cleanliness of the streets was imperative if we would prevent phthisis and other diseases, and he suggested that the water from the rivers be used for flushing them, and thus cleaning them without raising a cloud of dust-carrying germs.

The President thought that the most important point brought out in the paper and discussion, aside from points emphasized at the previous meeting, related to the ingestion of tuberculous milk and meat.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE INFLUENZA EPIDEMIC—SPLENIC ANÆMIA—CHANGES IN THE BLOOD IN THE COURSE OF RHEUMATIC ATTACKS—LONDON FOGS—GRESHAM COLLEGE AND THE NEW UNIVERSITY—DR. BROADBENT.

London, February 13, 1892.

The influenza epidemic is now decidedly on the wane, both in London and in most parts of the country. In the metropolis the number of deaths last week was only 314; in the two preceding weeks the deaths were 506 and 436 respectively. The diminution in the mortality which had marked the week before last was therefore more than maintained. About half the deaths were those of persons sixty years of age and upward. The mortality from respiratory diseases generally has also become much less.

At the last meeting of the Medical Society Dr. Walter Carr gave an account of thirty cases of splenic anæmia which had passed under his observation at the Victoria Hospital for Children. The ages of the patients when first seen varied from two months to two and a half years. The patients were usually wasted, and hemorrhages and irregular attacks of pyrexia occurred in the more severe cases. The red blood-corpuscles varied in number from thirty two to seventy-eight per cent. of the normal, but the white corpuscles were only slightly in excess, averaging about one white to one hundred red. Ten of the cases were known to have died, and a necropsy was obtained in seven cases. The enlargement of the spleen seemed to be due to simple hypertrophy, with some increase of fibrous tissue. The liver was not distinctly enlarged in any case, and no marked change was found in any other organ. Dr. Carr remarked that the disease was differentiated from splenic enlargement due to ague by showing no improvement under quinine. In fourteen cases there was evidence of congenital syphilis, but the spleen and the anæmia were not affected by mercury, so that syphilis could only be regarded as a predisposing cause. Rickets was present in twenty-seven cases, but the author did not regard it as the real cause of the disease because, first, in most rickety children the spleen was not enlarged; second, there was no connexion between the severity of the rickets and the size of the spleen or the degree of anæmia; and third, in some cases there were no signs of rickets. He considered that splenic anæmia must be due to a separate cachexia, to which syphilis and rickets predisposed, but which required some further definite exciting cause for its development; this theory would account for the clinical and pathological similarities observed in all the cases, and also for the absence of improvement under the treatment usually beneficial for rickets and syphilis. Mercury, arsenic, and quinine appeared to be useless as remedies, but improvement sometimes followed the exhibition of large and increasing doses of iron.

Dr. Leslie Ogilvie said he was convinced that the splenic enlargement was associated with rickets. Dr. Colcott Fox evidently leaned to the same opinion. He remarked that the ages of sixty-three children with enlarged spleens whom he had observed ranged from four months to two and a half years—a significant fact, as that was the epoch of the bone changes in rickets. He regarded syphilis as the great factor in causing enlargement of the spleen with anæmia—possibly by predisposing to rickets. The President (Dr. Douglas Powell) suggested that the term "anæmia with splenic enlargement" would better describe the cases.

At the Medical and Chirurgical Society on Tuesday evening, Dr. A. E. Garrod (a son of Sir Alfred Garrod) read a paper on "The Changes in the Blood in the Course of Rheumatic Attacks." The paper was based

upon about eighty examinations of the blood of twenty rheumatic patients. As standards of comparison the author had made use of observations on ten healthy persons and ten chlorotic patients as standards for comparison. He found that an attack of rheumatism was always attended with a considerable and rapid diminution of the number of red corpuscles, which diminution commenced very early in the attack. The corpuscles were rapidly replaced when convalescence set in, but any fresh rheumatic manifestation was attended by a fresh fall, and in this way the phenomena of loss and repair might be repeated several times in the course of an attack. In prolonged attacks there was not a progressive diminution of the number of red corpuscles, but the numbers remained at or about an even low level. There was no real connection between the corpuscular variations and the temperature curve—the blood-changes being equally marked in afebrile cases. The author considered that the corpuscular variations afforded a far more delicate index than the temperature chart did of the activity of the rheumatic process. The blood-changes might be equally conspicuous whatever the nature of the rheumatic manifestation which they accompanied—whether arthritis, pericarditis, erythema, or pleurisy; they were not due to salicylic treatment, as they were equally well marked when no salicylate was given. A loss of corpuscles was sometimes observed when the patient first left his bed, but this was not a constant phenomenon. The variations of the percentage of hæmoglobin frequently followed those of the corpuscles—the worth of the individual corpuscle (obtained by dividing the percentage of hæmoglobin by the percentage of corpuscles) remaining constant. A tendency to falling worth was manifested in many cases. When the worth fell during the acute attack the diminution was usually only temporary, but a progressive fall might set in during convalescence and produce a condition of more or less chronic anæmia. Any conspicuous diminution of worth between the first and last observations was, nevertheless, exceptional. In a few cases the hæmoglobin percentage rose rapidly for a time, while the percentage of red corpuscles remained constant or was falling. Dr. MacMunn had pointed out that uro-hæmatoporphyrin was usually present in the urine in some quantity during rheumatic attacks. This pigment was one of the products of the action of reducing agents upon hæmatin, and it thus seemed probable that some connection might be traced between its appearance in the urine and the changes in the blood. To determine this question the blood and urine were both examined in eight cases, but it was found that the appearance in the urine, or disappearance therefrom, of uro-hæmatoporphyrin did not bear any recognizable relation to the corpuscular variations as to number and worth. Patients in whose urine the pigment was found throughout their stay in hospital, left the hospital with no deterioration of blood. Dr. Garrod hence concluded that—assuming it to be derived directly from blood pigment—the appearance of uro hæmatoporphyrin in the urine did not indicate excessive destruction of hæmoglobin, but rather a perversion of the ordinary processes for the elimination of the effete blood pigment. The anæmia of rheumatism was of two kinds—an acute oligocythæmia, which was rapidly recovered from, and a more chronic condition of pseudo chlorosis, which might outlast the attack, and which was only observed in a few cases. The first variety called for no special treatment, but iron was often of great value in combating the second and more lasting form of anæmia.

Dr. Willcocks said the blood-changes in acute rheumatism were very similar to those which occurred in other forms of fever, such as typhoid, pneumonia, etc. The red corpuscles became fewer and less rich in hæmoglobin. A few doses of iron could alter considerably the amount of hæmoglobin in the corpuscles.

Dr. Sturges referred to the anæmia accompanying acute rheumatism, and mentioned the cases of two children lately under his care. Both children were extremely anæmic. In one case there had been hemorrhage, but in the other there was no apparent cause for the anæmia. In both, however, pericarditis and endocarditis set in. He asked if, in these children, the anæmia might be considered as evidence of a rheumatic condition.

Dr. Ogier Ward mentioned the case of a child, seven years of age, with rheumatism, whose urine was dark-colored and of high specific gravity (1 030). As the child improved the specific gravity of the urine lessened, and Dr. Ward suggested that the specific gravity of the urine might assist in diagnosis.

In reply to a question in the House of Lords the Prime Minister has declined to assent to issue a Royal Commission to inquire into the London fogs, but has intimated his willingness to support the appointment of a Committee of the House.

The latest proposal with regard to the new university for London is that it should be termed the Gresham University. Gresham College in the city of London would be then incorporated with the university. The college has an ancient endowment which could be made available for the support of the new institution.

Dr. Broadbent has been appointed one of the Physicians in Ordinary to the Prince of Wales.

HOT SALINE INFUSION, ARTERIAL, WITHOUT CUTTING.

To the Editor of the Medical Record.

Sir: In your issue of February 6th is a letter by Dr. Julius Rosenberg which would seem to call for some reply at my hands. It is evidently my misfortune not to write English that is clear enough for this gentleman's comprehension. He begins as follows: "In the Medical Record, vol. xli., No. 1, appeared an article by Dr. R. H. M. Dawbarn on the surgical treatment of hemorrhage, in the course of which is advocated the infusion 0.6 per cent. saline solution at or above the temperature of the blood. Dr. Dawbarn also cites a case in which the value of this measure has been successfully demonstrated. This mode of treatment is not new, because experiments and cases have been reported since 1879."

I have nowhere made the ridiculous claim of novelty for saline infusion at, or slightly above, the normal temperature, performed by the customary technique of a cutting operation, with insertion of a cannula into the severed artery or vein.

Dr. Rosenberg sets up a straw man and then proceeds to demolish him. In this easy task he quotes a number of writers in 1879, '81, '82, who are quite devoid of present interest, their work being now well known to us all, old and musty. I did not mention them in my article because this was not meant for a repository of ancient physiological experiments. However, as a matter of thoroughness in reply, I shall presently allude to every author named by Dr. Rosenberg, so far as his writing bears upon the question under discussion.

Such small claim to originality of device as I did make was as follows:

"Now for the new and simple technique to which I alluded a few minutes ago. It involves no cutting whatever, no searching for a collapsed vein, no freshened knowledge of anatomy, no tying in of a cannula, no cannula at all, in fact."

My method is the introduction, *without cutting*, of an ordinary hypodermatic needle into the very largest artery accessible (the common femoral, just below Poupart's ligament, where its calibre is enough to carry a lead pencil easily), and forcing in some appropriate salt-solution, *extremely hot*, either by gravity or by the Davidson syringe.

It is wiser to employ the femoral than some lesser artery. In the latter case cutting is inevitable, as it is practically impossible to enter, say, the radial or ulnar with a needle, unless the artery is first laid bare. I have

tried it on the cadaver and find what I have said to be true. Then, too, if even so relatively unimportant an artery as one of these be divided, and a cannula tied in, there is risk of gangrene, as evidenced by Kümmel's case in which this resulted.

The theoretical objection that the hypodermatic needle may do serious damage to the femoral artery, I have met both by a successful case (published) and by the report upon Dr. Wyeth's patient, who bore Macewen's method of needling the diseased (aneurismal) wall of a still greater vessel; not one, but thirty-nine needles entering, at different times, each remaining in place twelve hours; and with distinct benefit noted a year later. It would seem a fair inference, therefore, that we need not fear a single needle puncture, in a sound vessel for a single half-hour.

For a surgeon there are no objections to the cutting operation, with use of cannula, etc., in, for instance, the median-basilic vein. But we may as well face the fact that there are many, very many, family practitioners who will, as heretofore, try everything else, and fail, rather than use a scalpel and attempt what they do not regard as an easy thing to do. The rarity of recorded cases of saline infusion in general practice proves this, if proof were needed, in a matter of such common knowledge.

To these gentlemen the entire simplicity of the device I have suggested will, I believe, commend itself, and hence be the means of saving many lives.

Of course, as I have elsewhere said, if the patient's circulation be not in an extremely bad way, the injection of salt-solution through the hypodermatic needle into the subcutaneous cellular tissue, here and there, would seem best of all. But when almost moribund, the needle in the artery leaves no chance for non-absorption of the injected fluid and is consequently wiser.

"To return to our mutton." Dr. Rosenberg mentions *Schwarz*, *Kronecker*, and *Sauder's* experiments. These gentlemen only reported work on the lower animals, and, of course, here tied in their cannulæ. *Ott* goes into full details in stating this same fact as to his own work.

In quoting *Kümmel's* two cases Dr. Rosenberg announces that this writer used a glass funnel, rubber tubing, and a large *hypodermatic needle;* and Dr. Rosenberg carefully avoids mentioning the cutting operation done in each instance. Upon looking up Kümmel's original paper, it is found that he specifically states that the artery is laid bare, tied, and a *cannula* (Kanüle) inserted.

Comment on this kind of criticism would seem needless.

By *Bishop* I presume Dr. Rosenberg means Bischoff, whose work is in the same line with the preceding.

Küstner, also, in his reported case out of Schulze's clinic, cut down, tied the radial artery, and after opening this vessel fastened in it a cannula for injection.

Dr. *Munchmeier's* paper is a very interesting and comparatively recent one, and I was glad to know, through Dr. Rosenberg, where to find it. It deals exclusively with subcutaneous saline injection (into connective tissues) and therefore does not touch upon this question at issue.

In no case mentioned by my ingenuous critic, nor any so far found by me, have I noted the use of the method heading this letter. I shall be glad to report it, if I read of such a case, and to give due credit therefor.

Regarding the question of the heat of the fluid injected, the hottest temperature mentioned by Dr. Rosenberg is 40° C. (104° F.). This, of course, is no exemplification of the principle which I have urged; which is the use of water as hot as the hand can possibly tolerate, as a stimulant to the heart and a means of restoring the vascular tone, the loss of which is so perilous a factor both in shock and hemorrhage. Let me finish by quoting the final sentence of my argument upon this matter:

"*A priori*, it would seem safe to employ this salt-water as hot as the hand can possibly bear, which is about 49° C. (120° F.); since globulin coagulates only at 70° C. (158° F.), and serum-albumin at 72° C. (162° F.); or about forty degrees Fahrenheit hotter than the hand can support."

Very respectfully,

ROBERT H. M. DAWBARN.

345 WEST FIFTY-SIXTH STREET, NEW YORK, February 17, 1892.

THE NON-CONTAGIOUSNESS OF LEPROSY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In your issue of a week ago you did me the honor to notice my article, read recently before the County Medical Association, "On the Non-contagiousness of Leprosy," and in the last issue appears a letter from Dr. Allen, relating to the subject.

As there appears to be some misunderstanding with reference to my position in the matter, I beg leave to say a few words concerning the subject in question.

It was unfortunate that, owing to press of work, the article was not made ready for the press, so that those who wished to comment might see the article itself, rather than any notices of the same. It is, however, already in type, and is expected to appear in the next number of the *International Medical Journal*, of Philadelphia, when I hope the criticisms, if need be, will be based upon a careful study of the article itself.

I have never taken an ultra position in regard to the subject of the non-contagiousness of leprosy, but having studied the matter for many years, and having observed a very considerable number of cases in this country and elsewhere, and also having had some experience regarding the personal fear and dread of the disease in connection with the management of the New York Skin and Cancer Hospital, I felt that it was but right to present the non-contagious aspect of leprosy, in its strongest form, in order to allay the unnecessary excitement which some rather rash individuals have seen best to stir up of late years.

Will you allow me herewith to present the conclusions with which I closed my paper, in order that your readers may see exactly the position I did take?

"In conclusion, I may briefly state the results of our study, as follows:

"1. There is no warrant for the popular terror surrounding the name of 'leprosy' as a disease.

"2. The disease is not contagious in the ordinary acceptance of the term, as applied to such diseases as smallpox, scarlatina, or syphilis.

"3. Leprosy is probably due to the presence of a bacillus.

"4. There is strong reason to suspect that it may first be introduced into the system by the way of food, and fish is the most likely of all substances to furnish and convey the poison.

"5. There is evidence that when acquired, the disease may, under favorable conditions, be transferred from one person to another.

"5. Heredity probably accounts for a share of the cases, but the disease is not necessarily transmitted by inheritance.

"7. Inoculation with leprous matter may be the means of conveying the disease, when all the conditions are favorable.

"8. There are far more and greater reasons for the restriction of syphilis and tuberculosis by isolation and segregation than for the necessity of these regulations in regard to leprosy."

In my paper I have elaborated, to some extent, the arguments in favor of the fish hypothesis of the cause of leprosy, and feel that this matter has, as yet, by no means received the serious attention which it deserves.

I must still adhere to my view, after very considerable study of the matter, that the disease has not been spreading by direct contact with the leprous patients, although, all must acknowledge that it is highly probable that the disease is extended by the transference, in some way or

other, of the bacillus to those non-infected. But, in view of the very great length of the period of incubation, I hold that it is not proven that any number of individuals have ever acquired the disease from direct contact with others affected, or that it has ever been traced, in any proportion of cases worth mentioning, directly from one person to another.

In view of the serious ravages made by syphilis and tuberculosis in this community and elsewhere, I feel that I am more than justified in making my last conclusion, that these should far rather be restrained than leprosy.

I remain, Yours very truly,

L. DUNCAN BULKLEY, M.D.,

4 EAST THIRTY-SEVENTH STREET, NEW YORK.
February 15, 1892.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of January 23d appears a notice and short abstract of a paper read before the New York County Medical Association, on the above subject, by Dr. L. Duncan Bulkley, and his conclusions are as follows: "1, That there was no warrant for the popular theory that leprosy was a contagious disease; 2, the disease was not contagious in the ordinary acceptation of the term, or as that word was applied to small-pox, syphilis, etc.; 3, it was probably due to the presence of a bacillus; 4, there were strong reasons to suspect that the bacillus might be introduced into the system by way of food, especially drink; 5, there was evidence that the disease might, under favorable conditions, be transferred from one person to another; 6, heredity probably accounted for a share of the cases; 7, there was no necessity for segregation; 8, there was far more reason for placing restrictions about patients with syphilis and tuberculosis than about those suffering from leprosy."

Naturally one hesitates to inflict upon your readers one's views, and no less so in contravention of Dr. Bulkley, yet to much contained in these conclusions I must dissent. I do this from a feeling of having good company in my beliefs as well as indulging the hope that some good always comes from a little free discussion and criticism.

In the first place, what do we mean by the word contagion? In authoritative dictionaries one finds various and circumlocutory definitions, this word and infection interchanged and mixed, and with explanations the longer they grow so much the thicker the haze. However, it is finally made out that the common acceptation is that property or quality by which diseases are transmitted or spread without actual contact or touch. Bitter controversy and dissension have always marked the use of this word; even now learned professors seem to be not quite sure of their ground when coming to it in their annual lectures before their classes; and for centuries long discussions and classic wranglings have gone on over its meaning. Dr. Bulkley's use of contagion, as applied above, must have for many minds more than one meaning—at least I am so unhappily placed. It is possible that as a profession we are doomed to eternal ridicule for our inexactness and inaccuracies, and may continue to the end of time with opinions as diverse as may be heard at almost every trial in court where "expert testimony" has full play for its peculiar inconsistencies; nevertheless, we must continue the endeavor of accommodating our opinions as best we may.

Dr. Bulkley says there is no warrant for the popular theory that leprosy is a contagious disease. In my opinion and experience there is such warrant, and I can name some most able and conservative men who have extensively handled this disease, and who believe in its contagiousness in the ordinary meaning of that term. Thin and Manson are among this number, and the latter's experience in the Far East has been rarely equalled by any European. Dr. Bulkley says it is not contagious in the acceptation as applied to small-pox, syphilis, etc. Now many or most of us believe that there is a vast difference in the quality and manner of contagion or infection, or whatever we may call it, by which these diseases are propagated. Small-pox may be communicated at some distance, I have seen it stated a quarter of a mile; I have heard of syphilis being caught in mysterious ways, but still strict propinquity seems essential in the experience of most medical men. Here is an elastic application of the word contagion. The third and fourth conclusions indicate something more tangible, and to which all must agree; sixth, heredity probably does account in a measure for a share of the cases, but it is not of more than minimum value, and vanishes in the absence of the essential cause—the micro-organism. Heredity accounts for the transmission of similar tissues and cell tendencies, but not for acquired characters or disease itself, in these post-Lamarckian times. The seventh and eighth conclusions are true enough, though the former has seemed necessary among degraded, ignorant peoples and aborigines by some very able and enlightened practitioners having to do with its management, whatever their opinions regarding the points in discussion.

If medicine has to any extent advanced in the world's estimation in the last quarter of a century, and this is conceded us, pathology in its larger sense has been the chief lever. Now to the mind of the student of pathology and bacteriology the use of the word contagion, so often seen, and as in some of the above conclusions, is like the hazy or vague impression many moderns have in mind when asked to define the genus "a pious man." It is a convenient mantle for inaccuracy, and in the case of the latter the mind only indefinitely has, or forms, a vague perception. Nobody denies, however, that there are contagions, or that "pious men" exist as well. According to our greatest pathologist, Burdon Sanderson, quite recently, "contagion is in its essence microphytic." Diseases are believed to be entities, and for the most part are extensions of the same producing elements—living organisms—at least the great mortality-causing ones are, and this argues a transferrence from subject to subject, and degrees of the process depending on many and complex conditions. That many escape is well known, and is no counter-argument; soils do not grow all seeds similarly, and conditions influencing their evolution on both hands constantly vary. If scarlatina is taken from long-put-away toys, hidden in garret nooks for years, we feel warranted in believing that the microphytic elements of the disease remained on those toys all that time; such an instance is known to me. Analogous phenomena are seen every day in the laboratory; no life manifestations occur unless allowed to do so, or the culture conditions are adequate. If syphilis requires contact of tissues or secretions of tissues to reproduce itself, and scarlatina and small-pox not such immediate or close contact, is it not an evidence of dissimilarity in the physical properties of their microphytic causes, such as gravity, form, and variations of vital phenomena, and persistence either in grown individuals or their spores? Hence varying possibilities of transferrence in the atmosphere, by food or drink, or by means of the common intercourse among families and communities, from breathing a common air to actual contact of persons and their secretions. Microbes do not take to themselves wings, but they do lodge on all things, on surfaces, and on dust particles, and there is abundant opportunity for such transferrence among human beings as the history of most diseases indicates without going into details. Because a disease is in its nature long continued or chronic, such as tuberculosis and leprosy, or even as syphilis; and though communicability is of a more insidious character, nevertheless this property, though not so striking in its effect as observed with the spread of the exanthems, still exists, and the word contagion ill defines our appreciation of the probable conditions. There is an increasing number of physicians who believe in the spread of typhoid by means of the atmosphere, yet who can doubt that were

this our general belief typhoid would be a "contagious disease" in our nomenclature?

I have seen leprosy in segregated communities, singly in cities, and in several countries, and I believe in its "contagiousness," that it is kept alive by the intercourse of the sick and the well, and that the power of its transferrence or communicability varies. It is transmitted by contact, as is easily observed in the Far East, where women resort to gatherings to allure men, believing that they will thus get rid of it. I have seen a young European woman, after a few years spent in India in mission work, with the beginning of ulnar anæsthesia. She was engaged in her work among lepers, but not many of them. There was association with lepers occasionally, but not close contact, to her knowledge. I have yet to see perfect segregation carried out anywhere, or isolation, and I have seen villages of as many as four hundred lepers in Middle China. It became possible for me, some years ago, in Egypt, to procure a tubercular nodule from a leper's hand, and within forty-eight hours the sections were observed under the microscope, and there is in my mind a very vivid impression of the disease cause and the possibilities of "contagion" or extension from such an individual among his associations, from the swarms of characteristic bacilli I then saw. We read of miasms, fish diet, old syphilis, and other causes, but the disease is not found without the organism. Marshes may be the original cause of the microbe in some lands, but it is unproven.

Pathology has recently taken syphilis back long anterior to our era, by the characteristic nodes on the dug-up bones of pre-Columbian aborigines. So, probably, this disease—leprosy—goes back with the rest of living things to its natural place. Since human tissues were formed, the elements of cell disintegration and protoplasmic variation were likewise in existence. There is no fish used in parts of the world where one finds leprosy villages. Syphilis is universal, but leprosy is not; the former is curable, the latter is not. We know that a characteristic microbe exists in leprosy, and that in the presence and under the influence of its products the cells composing the tissues cease to be able to preserve their normal functions and integrity; that this organism is not found otherwise; and that in most cases the thread of connection can be traced to another.

It matters little how the laws are made to discriminate in theory, the carrying of them out is wholly another matter and mostly an impossibility, but avoidance of those ill must sooner or later be done in communities, if this disease—among others—is to be abated. The active syphilitics and the tuberculous are now isolated in great part, or should be, and the greater care looking to isolation of leprosy is still more imperative, because of its insidious and longer incubation, its greater persistence, and incurability. I would refer Dr. Bulkley to Dr. Thin's book on leprosy, and to an article on its contagiousness, with an account of the origin and spread of the disease at Perean and Spain, in recent years, in *The Lancet* of January 16th, if he has not already seen it.

Respectfully yours,

C. A. SIEGFRIED,
Surgeon U. S. Navy.

NEWPORT, R. I., February 10, 1892.

A Precaution to be Observed in Douching the Peritoneal Cavity.—Dr. Alexander Duke, in a note to the *Lancet*, says that he has noticed that water just poured into the receptacle out of a boiling kettle will, when allowed to flow from the end of a rubber tube, be found almost cold for the first ten seconds or so. This is due to abstraction of heat by the six feet or more of tubing. It is a wise precaution therefore to allow the water to flow a while through the tube before using it in douching parts where a slight chill might be very serious, as in the abdominal cavity after laparotomy.

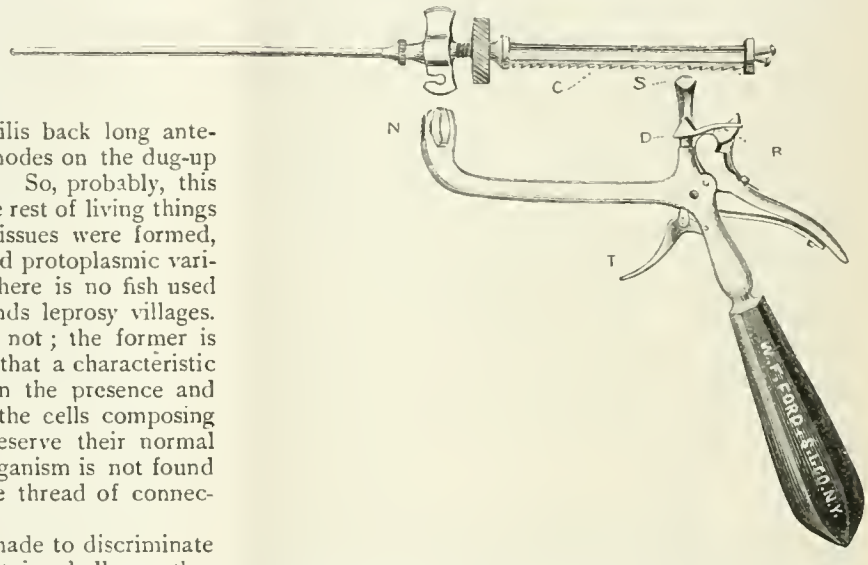
New Instruments.

A MODIFIED NASAL ÉCRASEUR.

By WILLIAM C. JARVIS, M.D.,

PROFESSOR OF LARYNGOLOGY AND DISEASES OF THE NOSE AND THROAT IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE.

THE device shown in the illustration is intended to be viewed, more as a mechanical adaptation or expansion than a change in the character of my écraseur. Since the presentation of this instrument to the notice of the medical profession, with the all-important No. 5 piano wire, upon which the utility of this and similar devices is dependent, I have endeavored, by the invention of accessory apparatus, to increase its applicability and efficiency to meet the various exigencies of intra nasal surgery. Many modifications have not been recorded by me for the reason that the mechanical alterations were not deemed sufficiently radical to merit especial mention. The improvement exhibited in the figure is believed to possess some intrinsic merit, and likewise successfully meets an objection, or perhaps, more properly speaking, a preference, which has been persistently urged against the universality of my écraseur's usefulness, namely, its



presence as an obstruction in the direct line of the operator's field of vision. This result is accomplished by the employment of an adjustable handle, exhibited drawn half-size in the figure, which when fastened to the écraseur substitutes the pistol for the pen-handle grip. The only change made in the original pattern of the écraseur, consists in the detachment of a toothed metallic strip to the movable cannula *C*, and the cutting of a slot in the finger-piece. In adjusting the écraseur to the handle, the cannula is merely slipped beneath the saddle *S*, and firmly fixed by the screw-nut *N*; in this position the ratchet *R* is enabled to act upon the cogged teeth *C* in conjunction with the detent *D*. It is obvious that pressure upon the lever supporting the ratchet must cause the cannula to spring forward, thereby contracting the wire loop, each successive advance being sustained by means of the detent. To remove the écraseur the binding nut is unscrewed and pressure exercised upon the trigger *T*, the result being a severance of the connection between the detent and the cogged teeth. Mindful of the readiness with which binding screws become detached and lost, the nut has been made inseparable. The changes impressed upon the original pattern of my écraseur to attain these mechanical effects, are so slight that Mr. W. F. Ford, the manufacturer of the instrument, informs me the necessary alterations can be effected with any of the old instruments in use, thus leaving only the adjustable handle to be procured anew. This device, it is obvious, is particularly applicable for the removal of gelatinous polypi, the rapid

excision of which, by means of the cold wire, never results in a significant hemorrhage. Experienced operators need hardly be reminded of the danger of utilizing this rapid ratchet motion for the removal of vascular neoplasms. The excision of nasal angiomata, for instance, or of even posterior turbinated hypertrophies, must naturally prove dangerous, by reason of the necessity of employing slow traction, in these cases, to prevent profuse hemorrhage. Should a vascular growth be included within the wire-loop, the operator may employ rapid traction until the resistance indicates a degree of constriction bordering upon incision, and then slowly complete the procedure by means of the milled nut with the adjustable handle attached to, or released from, the écraseur. It may be well to add a note of warning for the benefit of the uninitiated, with regard to the danger of confounding posterior turbinated hypertrophies with deep-seated gelatinous polypi, at least one instance being fresh in memory, in which a certain amount of unjust criticism, following in the wake of a severe nasal hemorrhage, was clearly due to this confusion. For further operative details, the reader is respectfully referred to articles, by myself and others, in the columns of the MEDICAL RECORD, and to Drs. Bosworth and Robinson's classical contributions on the naso-pharynx, published by William Wood & Co.

In concluding, I will add that a penchant, observed to exist among some operators for snares similar to Wright's, Mackenzie's, Allen's, Butlin's, and others, is believed to have been fully satisfied by the écraseur just described.

142 MADISON AVENUE.

THE OPHTHALMOLOGIST'S ANTISEPTIC CAP.[1]

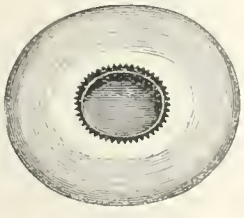
BY GEORGE E. ABBOTT, M.D.,

NEW YORK.

IN these days of sepsis, a-sepsis, and anti-sepsis, it is an interesting study to observe the non-observance, the partial observance, and the rigid observance of all those rules and procedures which science has elaborated and demonstrated as necessary to secure those results, which were formerly almost impossible and decided exceptions, but which are now the rule.

The old question of surprise, "How did you get such and such a result?" has become, "Why did you not get such and such a result?" It is your business to get it.

I cannot think that the difference between the thorough preparation of the gynecologist, who scrupulously prepares his surgical field and carefully surrounds it with an environment of thoroughly aseptic towels, etc., and the apparent thoughtless preparation of many ophthalmologists, who wash the eyelids but disregard the face, and especially the hair, ears, etc., and seem to care little for the environment, is due to a non-belief on the part of the latter in anti- and a-sepsis; but rather to the mechanical difficulties of properly guarding the head.

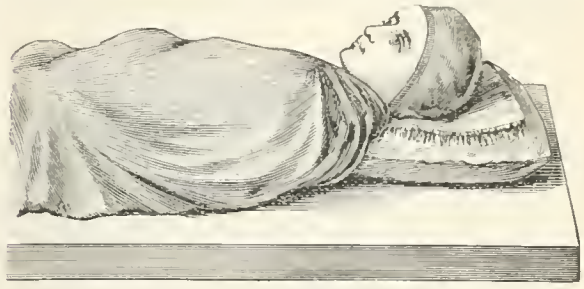


Being somewhat interested in the surgery of the face, I have studied into the ways and means of securing an aseptic environment for the head during surgical operations upon the face.

Mr. Williams, of the Williams Rubber Co., of this city, has kindly constructed for me these rubber caps which I now show to you. They may be had of him or at any of the instrument stores. They may be scrubbed inside and out. They are elastic, and will fit any head, male or female. They should be carried over the hair to its margin, all around, and may cover one or both ears; thus rendering all sepsis from hair and ears impossible, without the danger (especially to ladies) of catching cold after washing the hair. One may also be drawn over the beard if necessary.

[1] Presented to the Medical Society of the County of New York.

This rubber protection has surgical applications to other parts of the patient and to the operator as well, who may wear one himself while bending over the surgical wound. I believe this rubber cap will prove an important factor in reducing the percentages of those cases which "have not done quite well," or where "almost all



Cap and Sheet of Rubber Tissue.

the wound united by first intention," or when "there was just a little pus around one of the sutures," etc.

"The method in my madness" in calling this "the ophthalmologist's antiseptic cap" is, of course, simply to have it properly indexed so as to call their attention to it. If it shall prove to be of service to the ophthalmologists, I shall be glad, as I am indebted to some of them for many acts of kindness.

19 EAST SIXTY-FIRST STREET.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 27, 1892.

	Cases.	Deaths.
Typhus fever	22	4
Typhoid fever	11	12
Scarlet fever	230	29
Cerebro-spinal meningitis	1	2
Measles	295	10
Diphtheria	133	31
Small-pox	2	3
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Gallacetophenon is the name of a new remedy which Neucki has recently introduced, and which is said to be very efficacious in the treatment of psoriasis and parasitic skin diseases. It is said to be quite as active as pyrogallol, and does not have the disadvantage of staining.

Chancre of the Tongue is rare, according to Fournier, although the most frequent of extra-genital chancres after that of the lips. It is usually situated on the anterior portion of the organ, and is almost always single. Two initial forms are found, the erosive and the ulcerating, the former being much more frequent than the latter.

Secondary Syphilides of the mouth, Fournier says, form two groups, the moist syphilides and the dry syphilides. The first constitute mucous patches with their well-known various forms; the second, less well known, have received different names, such as syphilitic psoriasis, smooth plaques of the tongue, or ring worm-like syphilides.

The Mechanical Treatment of Constipation.—Dr. Feilchenfeld has employed in chronic constipation of women after childbirth, in hæmorrhoids, and in heart and kidney affections, the plan of placing upon the abdomen

a shot-bag weighing three or four pounds, and leaving it often over night, if necessary, but usually finds that after an hour's time a regular passage is secured.—*Centralb. für Gynäkologie*, No. 50.

Treatment of Chlorosis.—Dr. Váczi recommends for chronic chlorosis three Blaud pills daily, and ten drops of the following:

℞. Tinct. strophanthi,
Aq. amygd. amad. .... āā 3 ij.
—*Centralb. für Gynäkologie*, No. 50.

Hydrastis in Obstetrics.—Dr. Botti has found hydrastic canadensis, in daily dose of from one to two hundred drops, an excellent hæmostatic in the uterine hemorrhage of childbirth, as well as in ante- and post-partum bleeding. He regards hydrastis as much superior to the secale preparations, and free from their disagreeable effects.—*Centralb. für Gynäkologie*, No. 50

Antiseptic Mouth-wash (Muller).

℞. Acid thymic.....	0.25.
Acid benzoic.....	3
Tinct. eucalypti.....	15.
Spt. vini rect.....	100.
Essence. menth. pip.....	0.75.

M. S. Drop enough into a glass of water to cause turbidity, and rinse the mouth morning and night.

Perkinism.—Not far from a century ago the civilized world was ringing with the praises of "Perkinism." The story is old and oft-repeated, but will bear a brief retrospect. Elisha Perkins, then living in Connecticut, had introduced to public notice his "tractors" or "pullers-out of-disease," with which he cured many cases of rheumatism, gout, and disorders of the nervous system, by the application of these tractors to the body. The apparatus consisted of two pieces of metal (brass and steel) highly polished, to appear like gold and silver. They were made in a small village near New Haven at a cost of twelve and a half cents a pair, and were sold by Perkins for twenty-five dollars. Perkinism spread rapidly and soon made its appearance in England, where a Perkinian Institute was founded, and reports of five thousand cases were published. Certificates were obtained from the highest sources, and Perkins soon found himself the possessor of a fortune. The Archbishop of Canterbury was implored to compose a new prayer, to be used in all the churches, that no evil powers might be allowed to impede the magic workings of the inestimable gift of Perkins. The exposure of the Perkins fraud was the work of two physicians, who substituted two bits of painted wood, made to resemble the metallic tractors. With these they wrought many marvellous cures, and published a volume of reports upon them. When the true character of these substitute tractors became known Perkinism was no more.—Dr. S. W. Abbott, in the *Boston Medical and Surgical Journal.*

The Fate of a Small Boy with a Cigarette.—In a pamphlet entitled "Tobacco, Insanity and Nervousness," recently published by Dr. L. Bremer, of St. Louis, it is boldly stated in large type that "the boy who smokes at seven will drink whiskey at fourteen, take to morphine at twenty or twenty-five, and wind up with cocaine and the rest of the narcotics at thirty and later on."

ON HEREDITARY CHOREA, WITH A REPORT OF THREE ADDITIONAL CASES AND DETAILS OF AN AUTOPSY.[1]

By WHARTON SINKLER, M.D.,

PHILADELPHIA, PA.

PHYSICIAN TO THE PHILADELPHIA ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES, AND NEUROLOGIST TO THE PHILADELPHIA HOSPITAL.

THIS affection is one of considerable interest, partly on account of its rarity, but more especially from the peculiar and unvarying symptoms in every case which is met with.

The disease was first described by Dr. C. O. Waters, in a letter to Dr. Dunglison, which was published in his "Practice of Medicine," in 1841. It was also detailed by Dr. Charles B. Gorman, in a thesis for the degree of Doctor of Medicine, at the Jefferson Medical College, and referred to by Dr. Dunglison in the same volume of his "Practice." Dr. Irving W. Lyon reported some cases in the *American Medical Times*, in 1863, but it was not until Dr. Huntington, in 1872, read a paper on "Chorea," in which he mentioned the hereditary type, that the disease attracted any attention. From that time numerous cases have been reported, and the name of Huntington's chorea is frequently applied to the affection.

The choreic movements in this disease are much like those of St. Vitus's dance commonly met with in children, but they vary in certain peculiarities. They are more constant, more excessive, more rhythmical, and less under the influence of the will than in Sydenham's chorea. The patient is continually repeating the same irregular, jerky movements while sitting or standing, but when he attempts to walk the normal gait is interfered with by the grotesque and involuntary movements which are interposed. For example, as in the case of two of the patients, whom I shall describe later, when told to walk they would take a few steps quite naturally, then suddenly one leg would be violently thrust forward and the other brought up to it quickly with a little hop like a dancing step, then a few more sedate steps would be taken, to be again interrupted by the dancing step. Several writers have referred to this peculiarity in the gait.

In hereditary chorea, as the name implies, the disease is handed down from one generation to another; but we must bear in mind the distinction between hereditary chorea and the hereditary tendency to chorea. In the one the disease occurs in one generation after another, from father to son, or daughter, and following the same type; in the other, the disease presents itself in several children in the same family, differing perhaps in degree, and very frequently with no history of chorea in preceding generations, but instead, a history of some other neurosis. It is said that if the disease fails to appear in one generation all succeeding generations of this branch of the family are exempt from it. This, although generally the case, is not an unvarying rule.

The disease does not occur until middle life, beginning at about thirty-five years of age, and is essentially chronic. It never gets well, although there may be periods of relief, but, as a rule, it steadily goes on, getting worse until the death of the patient. This may not occur for many years, the disease lasting ten, fifteen, or even twenty-five years. Mental disturbances are common. Sometimes there are delusions of grandeur, and an elevated opinion of personal attraction, etc., and sometimes there is melancholia or dementia.

In September, 1888, I read before the American Neurological Association a paper [1] on "Hereditary Chorea," and recorded the histories of two new cases. Before that time only twelve different authors had reported cases, occurring in fifteen different families; but since then there have been extensive additions to the literature of the subject, and many cases have been reported in all parts of the world. A number of these cases have been found in insane asylums.

Klippel [2] relates a case of this affection in a man in whom there were irregular muscular movements beginning at the age of fifteen years. These increased in severity, but he remained in the army until the age of twenty-four years, when his condition was such that he was unfit for the service. The patient had always been irritable, and when he came under observation at the age of twenty-nine, he was morose, suicidal, and subject to attacks of violent rage. He was suspicious, and constantly thinking that someone was going to injure him. There was general chorea of all the muscles of the trunk, extremities, and face, and well-marked facial asymmetry.

Suckling [3] adds a case of hereditary chorea in a man of thirty-nine, who had been affected since about thirty-five years of age. The patient's mother died at fifty-six, having been choreic for sixteen years; and one of his sisters, aged thirty-eight, had had the disease for five years. Suckling states that a daughter of the patient, aged twelve years, was also choreic.

Theodore Diller, M.D., in a paper on this subject,[4] gives the histories of five cases; three of these were patients in the Iowa Hospital for the Insane, two of them being brothers. Another case was communicated to the author by Dr. G. Alder Blumer, under whose care he was in the State Lunatic Asylum, Utica, N. Y. The fifth case was under Dr. Diller, in the State Asylum for the Insane, Danville, Pa. This patient was one of a large family, ten in all; five of them were choreic.[5] Of the relatives of this patient, the father, two paternal aunts, and two paternal uncles had the disease. The grandfather was also choreic. The affection had begun at about the age of forty, and she had been affected mentally since the beginning of the chorea; she was melancholic and subject to fits of anger, in which she had threatened to poison her neighbors, and did attempt suicide. Diller, in this paper, expresses his doubts as to there being any difference in the essential characters of hereditary chorea and the ordinary chorea of children. He prefers to call them varieties of the same affection. It is true that the multiplication of the nomenclature of disease is undesirable; but the differences in all of the features of the two forms of chorea are so great that they are practically different affections. When the morbid anatomy of the disease has been studied sufficiently, no doubt there will be marked pathological differences found. W. P. Herringham, in an admirable paper on this subject,[6] expresses himself as follows: "The conclu-

sion which comparison suggests is, that the two, that is, hereditary and Sydenham's chorea, are produced by affections of the same parts, but of a different nature."

In an interesting paper by Diller,[1] on "Chorea among the Insane," the writer records thirty-nine cases; of these thirty-three were furnished by the medical officers of twenty-three hospitals to which Dr. Diller had sent a circular asking for information on the subject. Of these there were but three cases of the hereditary form. These were reported by Dr. Diller in his paper already referred to. Dr. Diller's conclusions are that chorea is more common among the insane than is usually supposed. In the twenty-three asylums from which he got replies to his letters of inquiry, there are sixteen thousand four hundred and ninety-nine inmates; among these there were thirty-nine choreic, or a proportion of 1 to $423\frac{2}{3}$. I cannot agree with Diller that in all long-standing cases of chorea there is more or less marked tendency to mental deterioration. There are many cases of chronic chorea in which the mental condition is normal, and I recall the case of a man of thirty-four, who had been choreic from birth, who was, as far as could be observed, normal mentally, and was able to support himself by the business which he carried on.

Bower[2] records three cases of this form of chorea. The first was in a negro, not a full-blooded African, however. The patient has almost straight hair and a copper-colored skin. His mother, her two sisters, and one brother had the same affection. The patient was thirty-six years of age, and the disease had begun at about thirty. He had been a hard drinker, and had a history of paraplegia, coming on when he was twenty eight and lasting about three months. The movements were constant and characteristic, and his speech was slow and hesitating. His mental condition was unaffected.

Bower's second case presented all of the features of hereditary chorea, but there was an absence of a history of the disease in any branch of his family. The patient was thirty-two years of age, and there were twitchings and irregular movements beginning at twenty-nine. He had no evidences of mental disturbance. The third was a woman, forty-one years of age, in whom choreic movements began at the age of thirty-six. Her father had the same affection, and what is very interesting, her baby of four months had almost constant choreic twitchings of both hands. In this patient there was slight beginning dementia. All of these patients were in the wards of the Philadelphia Hospital.

Korniloff, a Russian, has reported a case of hereditary[3] chorea. Hay, in a valuable article,[4] adds to the literature of the subject six cases which have come under his observation in the State Asylum for the Insane, Morris Plains, N. J., and gives notes of two more cases which were in the same institution a few years previous, making eight additional cases in all. All of these patients were taken to the Asylum for mental diseases. It is singular that so few cases of this disease have been reported from other hospitals for the insane. In Diller's cases, referred to above, there were but five cases of the hereditary form of chorea among the thirty-nine adult choreas which were found among the inmates of twenty-nine asylums. Hay's cases are all well-marked examples of the disease under consideration, and all of them had a family history of chorea going back one or more generations. In one patient the choreic movements did not become constant until nearly her sixtieth year, although there had been several brief attacks previously. Another case became choreic at fifty-three years of age. The daughter of one of these cases became choreic before the age of twenty. In two of Hay's patients there was a history of acute rheumatism, and in two others, in which there was no record of rheumatism, there were cardiac murmurs.

Clarence King[1] makes a third communication on the subject of hereditary chorea, and gives the histories of two additional cases, a brother and a sister; both were insane, and were inmates of the Cattaraugus County Insane Asylum, N. Y. The maternal grandmother was the first among the ancestors in whom the disease could be traced. Mrs. S——, one of the cases, had the disease since she was twenty years of age, and was in the ward for imbeciles. Her brother, Henry C——, was sixty years of age, and had been choreic for fourteen years. Two of his children were said to have unmistakable signs of the disease, their ages being eighteen and sixteen years.

Dr. William Osler[2] reports the case of a man, aged fifty-nine years, who had had chorea for eight years. He had general irregular movements and his gait was peculiar. He walked with steps of irregular length, halting occasionally, and with stiffness of the legs. The reflexes were increased and there was slight ankle clonus. Four or five other members of the family were similarly affected. The expression was fatuous, and the mental condition was considered weak.

Arostegui[3] reports two cases. The details of these are not given in the abstract, which is the only report to which I have had access.

Biernacki[4] describes the case of a man, of forty-eight, who had been suffering from choreic movements for five years. His mother and maternal grandfather had had the same affection. His memory was considerably impaired.

Jolly[5] reports the following case: "Woman, thirty-five years old. Disease began at twenty-seven years. Patient gives as cause death of husband. First symptoms said to be twitching of face, but may have begun in leg. Finally the twitchings extended throughout the entire body. At the present time the rather anæmic woman presents the appearance of a rather severe case of ordinary chorea minor. The muscles of the face, trunk, and extremities are in constant movement. The brows are raised, mouth grins, eyes roll, and tongue protrudes in quick succession. The gait is rocking, the steps dancing and scraping, and sometimes, on account of sudden motion of the trunk or strong flying out of a foot, the gait is interrupted. The speech is often cut short by the smacking of the lips or sudden inspiration, as in many cases of acute chorea, while no true disturbance of articulation exists.

"The patient can, when comfortably quiet, write her name and short sentences. During sleep the motions cease. Mental disturbances of two kinds are recognizable. She herself complains of loss of memory, which can also be objectively proved. The statements as to the history of her disease are unsafe and incomplete, and sometimes fabulous. She is very weak in reckoning, while formerly she was quick and intelligent. For the rest, she is by no means to be regarded as imbecile. The second mental disturbance concerns the emotional sphere. She is very irritable, easily led to tears, and often much depressed. At these times the choreic movements increase. Her previous temperament is said to have been quiet. The mother of the patient and two brothers of the mother suffered from the same disease. The mother became ill, in her thirty-fifth year, in the same manner as the patient, and suffered till her death, aged forty-six years. In her, also, loss of memory was marked. In her later life she was feeble-minded, and at times maniacal. An elder brother of the mother became ill later than she, eight years before his death, from chronic chorea. He became imbecile. A younger brother of the mother will be exhibited by Dr. Remak. In this patient the chorea is less than in ——, and the mental affection is also less. Four

brothers and sisters of the mother remain healthy. The patient has two sisters, aged thirty and twenty-five years, of whom the last suffers from migraine. In her generation she is the only one affected with chorea. Of the two living children of the patient, girls of ten and eleven years, the elder has suffered from chorea for two years, and is said to have had epileptic attacks for the same length of time."

I have had under my care, in the nervous wards of the Philadelphia Hospital, in the past two years, three patients with hereditary chorea, whose cases have not yet been reported. I am indebted to Dr. Alexander and Dr. John H. Rhein, internes of the Philadelphia Hospital, for the histories of these cases.

Case I.—William D——, aged sixty-three, pedler by occupation. Admitted to the nervous wards of the Philadelphia Hospital, July 16, 1889. The patient knows of no disease in the family except the one with which he is affected. He states that his mother had the same affection. He thinks that in her case it came on late in life, and he knows that it continued until her death, which was at the age of about seventy. In his mother's case there was a general tremor, not so irregular, he says, or extreme, as in his own case. He knows of no other member of his family being affected with any nervous disorder. Patient has always had good health. He has not been intemperate or addicted to excesses of any kind. About fifteen years ago, that is, at the age of forty-eight, choreic movements began in his hands. There was at this time no cause to excite this condition. The movements gradually increased in extent, and by degrees involved the whole body, until the face and trunk became affected. About five years after the beginning of the trouble the irregular movements had extended to the whole body. He thinks that his disorder has been aggravated by treatment by arsenic.

Present Condition.—All of the muscles of the body, including the facial muscles, are involved in the choreic movements. There is continual twitching and jerking, and the movements are greatly exaggerated by any excitement. A strong effort of the will can control the movements for a short time, and during sleep they cease entirely. Speech is somewhat affected, his articulation being slow and halting. The knee-jerks are exaggerated, and all of the cutaneous reflexes are also increased. His mind is somewhat affected. He is not clear in giving an account of himself, but it is difficult to say whether he has any delusions. There is no pain, and no impairment of sensation. There are no bladder or rectal symptoms. His general health is good, and no disease of any of the abdominal or thoracic organs can be detected.

Case II.—Mary D——, aged forty-six, white; born in Ireland; occupation, housework. Admitted to the Philadelphia Hospital, July 20, 1890. Her grandparents died of old age. Mother died at the age of thirty, of consumption, according to the patient's statement. Five years ago her father had a stroke of paralysis. This was very slight, and kept him in bed only three weeks. He now walks well with the aid of a cane. His speech is slightly affected. She has two brothers, who are well and strong; one sister, who is dead, from causes unknown to patient. She says that her entire family is nervous, that is, all have slight tremor of the hands in holding the paper to read. She has had the diseases of childhood and small-pox; with these exceptions has always been healthy. She has never had rheumatism. Her menstrual flow was established at the age of fifteen; she has always been regular and there has been no dysmenorrhœa. She still menstruates regularly. She has always lived with her father, who has abused her constantly She says, "he made a foot ball of her head." Two years ago he struck her an unusually hard blow on the side of her head. This hurt her very much at the time, but did not render her unconscious. A day or two after this she was asked by a neighbor why her head shook so much. She did not know that there were any movements. She soon found that her hands and the whole body were in constant motion. These movements do not tire her, and she is not conscious that they are made unless her attention is called to it, or she happens to look at herself in the looking-glass. She can read without difficulty. Her head is held a little on the right side, and has a constant back-and-forward or lateral movement. There are slight spasmodic inco-ordinate movements of both hands and feet, which can be arrested by attention or voluntary effort. The tremor is irregular and well-marked, without being coarse. Her gait is characteristic. She is able to walk, but after taking five or six steps in a deliberate fashion, there comes a long stride with one foot, then she brings up the other in a studied and measured way, much like a dancing step—then continues regular steps for five or six more, and again repeats the movement of bringing the second foot up, after a long stride. She cannot walk in a straight line, going constantly off to one side or the other. All voluntary efforts are slow and labored. The tongue is protruded well, but is not held out for any time, it being returned suddenly, and apparently involuntarily. Choreic movements affect the muscles of the neck. The head is constantly being rotated to the left and upward, and there is apparently some contraction of the sterno-cleido-mastoid muscle which holds the head even when not moving in the above-described position. The intellect is impaired. The patient is voluble, and often repeats pointless remarks. She is easily excited, and one day, after having been alarmed at the prospect of an electrical examination, she was much excited, talked loudly, acted strangely, and was very restless for two hours. The pupils are small, equal, and responsive to light. There is slight lateral nystagmus. The reflexes are everywhere exaggerated; sensation is everywhere good, and there is no loss in motor power. Her lungs and heart are normal, and her general health is fairly good.

Examination, July 17, 1891.—Patient's general condition is about the same as in the last note. The choreic movements are more extensive. The eyelids cannot be kept quiet, and the orbicularis oris is in constant motion. The movements of the arms are peculiar. The left arm is flexed at an obtuse argle, with the hand extended to a right angle, with the arm and the fingers partially flexed. This position is constant, the movements exaggerating the position. The forearm is also rotated, and the whole arm moved upward and a little outward. The right arm is usually extended, and the movements on this side are more typically choreic, that is, the arm is not held stiff. The body rotates on the pelvis. The legs are also affected, the movements consisting of flexing of the feet and rotation of the legs, the thighs being occasionally flexed a little. The knee-jerk is now sluggish, elbow-jerks normal. The plantar reflex is very active. The gait is as before described, all the choreic movements are exaggerated when she walks and cease during sleep. She complains of pains.

Case III.—John W——, aged forty-eight, white; native of Germany; occupation, carpet-weaver. Admitted to the Philadelphia Hospital, July 2, 1890. His paternal grandfather is said to have had the same form of chorea as the patient, but no data can be obtained in regard to his case. The patient's father began to show irregular spasmodic movements of the head and extremities when he was forty years of age. He grew progressively worse and died at the age of fifty years. One sister began to show symptoms of the same disease at the age of fifteen. She is still living, but is in Germany, and the patient cannot tell what her present condition is as he has not seen her for many years. When twenty-nine years of age the patient first noticed a stiffness in his arms and hands, so marked that he could not work with his usual ease. Soon after this he found that his hands were beginning to move about in an irregular manner. He did not feel the movements himself, and would not have known that they were

made unless he was looking at his hands. A year later the head became involved, and in a short time the movements extended to his legs. He has not been able to do work of any kind since thirty years of age.

Present Condition.—The patient is entirely unconscious of his movements. They do not cause him any pain, weariness, or inconvenience. The arms, head, and trunk are in continual movement, the movements being greatest if he is excited in any way; for instance, asking him questions will increase all of the movements to a marked degree. The movements are greater on the left side. He can feed himself, but with very great difficulty, and attempts at voluntary movements increase the chorea. His gait is peculiar and characteristic of the disease. It is very similar to the walk of Mary D——. In walking his whole attention seems absorbed by the effort. The step is measured and slow. The leg and thigh are first well flexed, then the weight of the body is slowly and cautiously thrown on one foot, the same movements being repeated on the other side of the body. After six or eight steps have been taken in regular succession, one foot is suddenly thrown forward, making a long stride, then the other foot is brought up to a short distance from the rear of the first. The regular steps are then taken for the usual time, to be again followed by the long strides. These long strides usually alternate, and very seldom do two occur on the same side in succession. The whole walk looks studied and much like a dancing figure. The tongue cannot be kept protruded. There is no loss of power and there is no loss of sensation. Reflexes: The knee-jerk and all of the other reflexes are increased. Ankle clonus can be developed. The plantar, epigastric, and cremasteric reflexes are exaggerated, as are the arm tendon taps. The pupils are equal and respond to light. His memory is considerably impaired, he is reticent, and never converses or reads. His speech is jerky and unintelligible. He has exhibited no delusions but his mental calibre is evidently far below normal. His appetite is good. There is marked constipation, but his general health is excellent. Although uncommunicative and having but little intercourse with the other patients he was cheerful enough, and when asked how he was, always declared that he was getting better. In March, 1891, he fell while going down-stairs and fractured the neck of the right humerus; although carefully dressed the bone did not unite. His condition remained about the same until May 14, 1891. On this day while sitting in the ward he fell from the chair to the floor, being apparently thrown by one of his choreic movements. He was able to get up, and with some assistance was got into bed. The next morning he was in a semi-conscious condition. There was no paralysis, no change in the pupils, and by arousing him he apparently understood questions but did not reply to them. When told to do so he put out his tongue, and if the arm were raised it would be held up for some minutes. He took nourishment when it was given to him. The stupor gradually became more profound and the patient died May 18th. From the time of the last fall until death the choreic movements ceased entirely. It was impossible to get the consent of the friends to make an autopsy.

These additional cases of hereditary chorea all bear a striking resemblance in their clinical features to those already published, and we are enabled by the increased material at our command to draw more definite conclusions than formerly.

1st. The fact of heredity is sustained. In one of Bower's cases, there was no history of the disease among the progenitors of the patient, but all of the symptoms were identical with those usually met with in hereditary chorea, and, as Dr. Mills justly remarked, "the disease must have a beginning," and this patient was probably the original case in his family. In one of my cases (Case II.) there is no clear history of heredity, but the symptoms are so typical that I think I am justified in classing it as a case of this disease.

2d. In most of the cases the disease began between the ages of thirty-five and fifty; but there are a number of exceptions to this rule. In one of Hay's cases the disease was not established until after sixty years of age, and in another, not until after the fiftieth year. In one of my last cases (Case III.), the irregular movements began at about twenty-nine years. Hoffman relates a case which began at ten years, and one who became affected while going to school. One of Lannois's cases developed the disease at twenty-one, and another, of Hay's, in youth. In King's last series of cases there are several in whom the affections began under twenty years of age. Mrs. S—— suffered from chorea for twenty years. Two of the children of Henry C——, the brother of Mrs. S——, were choreic at the age of sixteen and eighteen years. Suckling's patient had a daughter who was twelve years of age, and who showed, according to the author, unmistakable signs of the disease. Klippel's patient became choreic at fifteen years. A sister of one of my patients (Case III.) is said to have become choreic at fifteen years.

Mental disease occurs in most patients who are affected with hereditary chorea. In some the mental disturbance does not begin until the individual has been choreic for several years, but in others the insanity and chorea begin at the same time. Sometimes the want of mental equilibrium is noted first. The form of mental symptoms is generally of the same type. There is melancholia, with a tendency to suicide, irritability of temper, supposed delusions, and occasional outbreaks of violence are common. In the patients who have come under my own observation mental disturbance has been present, but has not been great. John W—— (Case III.) was melancholic, but had no delusions; and Mary D—— (Case II.) had mild dementia. In Huntington's patients, the two brothers, whose cases he related, there were delusions of grandeur; they thought they were captivating to the opposite sex, and made themselves conspicuous by their actions when in the street. This form of mental disorder is exceptional.

From a study of the cases now on record I have come to the conclusion that there are two forms of hereditary chorea, one in which the irregular muscular movements begin first, and, after a lapse of years, mental deterioration begins, and the other, in which the mental disease begins before, or simultaneously with, the chorea. The tendency to early or late development of insanity belongs to certain families. Rheumatism has occurred in a number of cases, notably in two of Hay's, and several patients have had valvular disease of the heart. The knee jerks are exaggerated in most of the cases in which the reflexes have been observed, and occasionally there has been recorded the presence of ankle clonus. King mentions a peculiarity in some of his patients which I have observed in two or three of mine. It is a tendency to stand in a certain position for long periods. For example, Mrs. S——, one of King's patients, was accustomed to stand for many hours, especially when trying to masticate food, with her body thrown forward to a level of her hips, and her arms extended backward by the side of the body, the palms looking upward. One of my patients, David M——, would stand leaning against the side of a building for long intervals. The gait in this form of chorea deserves especial attention, for it is so unlike that of Sydenham's chorea. In several of the cases that I have seen the walk was much alike. The description of it in the case of John W—— (Case III.) is quite accurate. It is somewhat like a dancing step, measured and studied, but with a sudden and quick change in the time. There is apparently little change in the sexual function; several patients are mentioned as having borne children after becoming choreic. The pathology is still undetermined, but there is no doubt that the disease is one of developmental origin.

I have had the opportunity of making an autopsy in one case of hereditary chorea. The patient was David

M——, whose case I reported in 1888.[1] He had suffered from the affection for ten years, and his death was due to exhaustion. He was worn out by the excessive movements, and during the last six months of his life gradually lost strength, and was finally confined to his bed, and died as a result of exhaustion due to the choreic movements, February 5, 1891. The skull-cap was extremely thick and the diploë was absent; the dura was adherent in places and was thick and tough; the meninges were congested and there was considerable œdema; the brain and cord were removed together. The membranes of the cord were congested, and to a small extent were adherent. There was no gross lesion observed, but the brain was not cut for the reason that it was preserved for later examination. The kidneys weighed about three and a half ounces each; the liver two pounds and five ounces. Though there was some slight sclerosis of the organs, there was no pronounced lesion anywhere found. The brain, unfortunately, was preserved in chloride of zinc solution, and therefore was useless for microscopic examination. The cord, however, was well preserved in Muller's fluid, and through the kindness of Dr. William M. Gray, of Washington, I am able to present these beautiful sections. The sections were examined under the microscope from the lumbar, dorsal, and cervical cord, stained with borax-carmine, and by Weigert's method. Macroscopic sections treated by the latter method show the following: All take the blue-black stain well in the posterior columns, while the remainder of the white matter stains poorly, especially in the dorsal and cervical regions. In the carmine sections the antero and lateral white matter stains too deeply, this again being most marked in the dorsal and cervical regions. The region of the central canal also stains a deep red. The cross sections are symmetrical in outline. Delineation of white and gray matter good. Microscopically the posterior columns are normal, except possibly a very slight increase of connective tissue in spots. In the remainder of the white matter there is considerable increase in the connective tissue. The walls of the blood-vessels are thickened, many axis-cylinders are missing, but never enough to completely cut off the tract. Motor-cells and nerve-roots normal. The region of the central canal is largely occupied by a mass of nuclear tissue similar to that found in normal cords, but the mass is far larger than usual, and stains much more deeply in the cervical region. The canal itself is quite large and irregular in outline. In the dorsal and lumbar regions it is small, and in one section shows as two canals.

Whether the condition described above be developmental, or whether it is due to a slow inflammation or to other causes, we are unable to say. The important change seems to us to consist rather in that which has taken place in the anterior and lateral white matter than that of the central canal.

There are many points of similarity between this affection and hereditary ataxia, which is now well established as a disease due to defective development of the nervous system. A striking feature in the histories of all of these cases is the marked neurotic taint through their families. Insanity, epilepsy, intemperance, and vice are prevalent in the family history. Hay calls attention to the frequent association of phthisis in the family. King refers to a circumstance to which I also alluded in my previous paper, namely, the probability that many, if not most, of the cases reported in this country are of common ancestry. East Hampton, L. I., according to King, was settled in 1649, and choreic families have lived there ever since. Several emigrations have taken place from there; one of them to Delaware County, N. Y., and it was from Franklin, Delaware County, that Dr. Waters's original observations were made. Charles B. Gorman, in his thesis, quoted by Dunglison, speaks of the affection existing in Luzerne County, Pa., which is less than seventy-five miles from Delaware County, N. Y. One of my cases was from Wyoming County, Pa., which adjoins Luzerne.

In closing, I would express the following conclusions: Hereditary chorea, while resembling in many respects Sydenham's chorea, differs in so many of its features that it is essentially a distinct and separate affection; that while, as a rule, there is remarkable uniformity in the symptoms presented, there may be variations; for example, in the occurrence of the disease at or before puberty. That it is not an invariable rule that if the disease fails to appear in one branch of the family the descendants of that branch have immunity. That the arrest of the movements by voluntary effort is not a distinguishing feature of hereditary chorea, as in some cases voluntary effort aggravates the movements, and there are many cases of Sydenham's chorea in which voluntary effort arrests the movements for the time. That chorea among the adult insane is a different affection from hereditary chorea with insanity. That the evidence we have indicates that the pathology of the disease is a degeneration of imperfectly developed cells in the motor tract or in the cerebral cortex and in the spinal cord. The occurrence of the disease at an early age in children of some of the cases recorded is confirmatory of this view.

Paraplegia of Syphilitic Origin.—Dr. Boulloche gives statistics to show that in sixty two per cent. of cases the paraplegia shows itself during the first four years following the chancre. In eight instances it occurred in the first year. Retarded myelitis, that is, coming on long after the chancre, either in the midst of tertiary accidents, or after a long period of inactivity, is of very rare occurrence. Figures show that medullary affections seem to burst forth twice as frequently in those who have had no mercurial treatment, or only an insufficient treatment, as in patients who have been well cared for. Chronic myelitis is rarely fatal, but it is also rarely cured. It appears as though paraplegias accompanied by severe pains are benefited more by mercury than the others, perhaps because of the existence of a gummous or sclero-gummous meningitis. Acute paraplegias, of precocious nature and rapid march, do not get well. Improvement is frequent in the tardy forms.—*Journal de Médecine*, December, 1891.

SOMNAL: A CLINICAL AND EXPERIMENTAL STUDY OF ITS PHYSIOLOGICAL AND THERAPEUTIC ACTION.

By O. M. MYERS, Ph.D., M.D.,

ROCHESTER, N. Y.

Much interest has centred upon the new hypnotic, somnal, and clinical reports of its use, together with experimental data, are rapidly confirming, and even exceeding, the claims of its discoverer. The medical fraternity will gladly welcome this new-comer to its materia medica, as it seems to possess the properties of a hypnotic *par excellence*, without the distressing and dangerous qualities of other drugs of this class. All of these latter are notoriously uncertain and inconstant in action, and most of them, especially chloral and morphia, expose the patient to the dangers of habitual use. The administration of somnal is happily free from these unpleasant sequelæ. Since the time of its discovery by Radlauer, of Berlin, in the fall of 1889, the action of somnal has been rigidly scrutinized and impartially investigated, which has resulted in unqualified endorsement of its efficiency and reliability; and its prompt and harmless qualities have been the delight of all clinical observers.

In selecting a drug of this class the careful practitioner will be guided in his choice, after satisfying himself of its hypnotic potency, by its correlative effect upon the circulatory and respiratory apparatus; and it will be the chief object of this paper to determine how much, and in what way, these important functions are influenced by somnal. If it can be shown, by experimental tests and clinical observation, that this drug, in therapeutic doses, has little or no effect in this direction, then somnal stands alone and apart from all other contestants for recognition as the only perfect hypnotic.

Physiological Action.—Locally, somnal is non-irritant. It has been noticed that at the point of hypodermatic injection, in animals, there was no evidence of irritation. Upon the mucous membrane of the stomach it has a slightly stimulating effect which serves to excite the secretion of the digestive fluids. In man, the ingestion of from two to three grammes results, within thirty to forty-five minutes, in a condition of quiet sleep, indistinguishably allied to natural sleep. The patient can be easily aroused to full consciousness, but if left alone, soon relapses to tranquillized slumber. The pulse in this degree of action is not perceptibly affected, but in some cases it may be found a little slower, with slightly lowered tension. The pupil is contracted as in natural sleep, and returns to the normal if the patient is aroused. Respiration is full and regular. When large amounts are given, the pulse shows momentarily an increase in rate and tension, but soon returns to normal; and if the dose has been excessive (℥ ij.) the arterial pressure may relax considerably and the heart-rate diminish notably. In such cases the temperature is slightly reduced, there is muscular relaxation and diminution of reflexes, and occasionally of sensibility.

Toxic doses, in animals, produce primarily an increase in the pulse-rate and blood-pressure, but, secondarily, notably diminish both. There is extreme muscular relaxation, weak pulse, pupils first contracted, then widely dilated, paralysis, coma, and death. Generally, respiration is first arrested and then the heart; although this order has not been constantly observed.

The Heart.—If the drug be directly applied to the heart of a frog, *in situ*, it will cause immediate diastolic arrest of that viscus and diminish, if not wholly destroy, the electrical irritability of the muscle-fibre. After the death of the batrachian, if a large amount of the drug has been applied to the heart, the latter fails to respond to the strongest electrical stimulus. It is therefore evident that the topical application of the drug exercises a decidedly depressing action upon the heart, destroying its susceptibility to nervous influences.

The Pulse.—If the dose has been sufficiently large the constant effect of the drug is to diminish the rapidity of the beat, which continues until the death of the animal. The exposed heart of the frog showed a diminution in the force of its contractions accompanying the retarded heart-rate; and in the case of a dog the tracings taken with the manometer indicated increase in the size of the pulse-waves under the same condition.

It will be seen by the foregoing that toxic doses of somnal exercise a decidedly depressing effect upon the heart, diminishing the number of contractions. How is this effect produced? I consider the action as twofold: 1. The drug acts, to a limited extent, directly upon the muscle-fibre of the heart, thereby diminishing its nervous irritability. 2. By stimulation of the cardio-inhibitory centres, for, when the pulse has been primarily depressed by the drug, and then section of the vagi made (thereby intercepting the inhibitory impulses to the heart) the cardiac rate and arterial pressure will instantly increase and remain so for a considerable length of time.

The following experiments (Nos. VI. and VII.) show that the heart-rate is diminished by the action of the drug after previous division of the vagi and the spinal cord, *i.e.*, independently of the extrinsic nervous mechanism of the heart.

The Arterial Pressure.—In ordinary doses in man, the blood-pressure is practically not affected, although in some instances a slight primary increase, with gradual return to the normal, has been noted. In other cases an insignificant lowering of the arterial tension has been noticed; but this, I believe, is due to the natural relaxation of somnolence. In a large number of experiments upon dogs (see Exp. No. VIII.) there has been constantly noted, first a slight rise in pressure, then a gradual lowering of the same. As the dose becomes toxic, the pressure will be seen to fall rapidly, continuing to do so in proportion to the amount ingested. It is probable that the slight primary increase in tension is not due to any direct action upon the circulation, but is the result of changes in the character of the respiration. This deduc-

tion is based upon the fact that in curarized animals this rise in the arterial pressure is not observed. The following experiment, selected from a number, illustrates the foregoing.

It will be observed that the application of a strong faradic current to a sensory nerve of an animal under the influence of the drug caused an immediate rise in the arterial pressure, indicating that the lowered pressure was not a result of vaso-motor paralysis. Other experiments show further, that previous section of the vagi, or division of both the spinal cord and pneumogastrics, will not prevent the fall of the arterial pressure in an animal strongly under the influence of somnal. It is concluded, therefore, that the lowered blood-pressure is not dependent upon vaso-motor influences, but is the result of direct action upon the ganglionic centres of the heart, and possibly upon the heart-muscle itself.

Respiration.—Somnal in full doses rather lessens the number of respirations per minute, causing them to become slower and fuller. Under toxic doses this effect is much more pronounced, the respirations finally becoming rapid, shallow and arhythmical, and finally cease. Section of the vagi (see Exp. IX.) does not prevent these phenomena, and this effect of the drug must, therefore, be the result of its action upon the respiratory centre in the medulla.

Summary.—1. Locally, somnal is non-irritant, exerting rather a stimulating effect upon the mucous membrane of the stomach. When applied directly to the heart of the frog, it acts as a powerful poison, destroying its electro-excitability.

2. In therapeutic doses the drug exerts no appreciable physiological effect upon the heart, and may be regarded as safe. Toxic doses depress that viscus: *a*, by direct action upon the muscle-fibre; *b*, by stimulation of the cardio-inhibitory centres.

3. Therapeutic doses have little or no effect upon the pulse-rate. A slight primary rise in the arterial tension may be observed, which soon returns to normal, or may even fall below—the latter probably due to muscular relaxation during sleep. Toxic doses rapidly diminish pulse-rate and pressure; probably due to direct action upon ganglionic heart-centres.

4. Ordinary doses cause the respiration to become slow and full. Toxic amounts induce rapid, shallow, and irregular respiration; the result of depression of the respiratory centre at base of brain

5 As, in therapeutic doses, sleep is induced without perceptibly affecting any other portion of the economy, it is fair to conclude that somnal acts directly and primarily upon the cerebrum.

Therapeutics.—The indication most promptly and perfectly met by somnal is to induce sleep, and it may be confidently relied upon by the prescriber in all cases where the insomnia is not the result of pain or syphilitic disease. As the nervous element predominates, somnal is the more certain to fulfil the requirements; as, for example, insomnia due to functional over-excitement of the brain after mental strain or anxiety, sleeplessness of delirium tremens, and in maniacal and hysterical disturbances. Its sedative and somniferent action is strikingly efficacious in the insomnia occurring during convalescence from acute disease. Where an adynamic condition exists, it must, of course, be used with caution. In whooping-cough, spasmodic laryngitis, asthma, "nervous cough," and chorea, it possesses decided sedative properties. A great element of safety is that the action of somnal, so far as I have observed, is never out of proportion to the amount ingested, nor does it act in a cumulative or other unexpected manner. The drug appears to possess little or no influence over insomnia due to acute inflammatory conditions.

THE MEDULLATED CORTICAL FIBRES WITH THE OSMIUM-COPPER-HÆMATOXYLIN STAIN—A PRELIMINARY HISTOLOGICAL NOTE.[1]

BY HENRY J. BERKLEY, M.D.,

BALTIMORE, MD.

AT the base of the gray matter of each of the convolutions lies an intricate mass of white medullated tubes of slightly different arrangement in the several parts of the cortex, as the callosal and other systems are joined with the fibræ propriæ. Most of these tubes are of medium fineness, dark contoured, with occasionally a well-defined branch from one of them visible, coming off at a T-angle. Very fine fibres cross the larger ones without any regular arrangement; their source is undeterminable, though probably they are collaterals from larger tubes.

Among the fibre masses may be seen occasional nerve-cells, some multipolar and quite large, others irregular in contour and smaller. The sharp distinction that was formerly made between the sub-cortical white and gray substances can therefore no longer be so sharply set, as the proportion of cells is in some places considerable.

The medullated tubes of the gray layers may be roughly divided into three principal systems—the radial, the inter-cellular, and the tangential or sub-pial fibres; besides which there are numerous scattered fibres that enter or come from the layers singly.

The radial shoot out from the sub-cortical white matter in two different ways, which unite to form the bands of vertically-directed fibres that are placed at almost regular intervals throughout the entire cortex. The first, the direct fibres, come off from the main mass at an acute angle, run closely together, and form a bundle that passes for some little distance in the inferior cellular layers without giving off many offshoots.

The fibres of the second variety are apparently much less numerous, join the bundles at an oblique angle some small distance from its base, and have a definite direction in their course. The two varieties form one compact bundle, which about the level of the fourth cellular layer begins to give off offshoots, each directed toward one of the larger pyramidal cells of the different layers. More numerous become these offshoots as the pyramidal cells in the mid regious are multiplied, until the band at the level of the upper layer of larger pyramidal cells finally dwindles down to three or four fibres.

Naturally it is not possible to trace each fibre to its cell, but a sufficiently large number were definitely made out to say positively such is the termination of the radial fibres. They seem to pass exclusively to these pyramidal cells, no exception to the rule being so far noted.

[1] The original method is given in The Johns Hopkins Hospital Bulletin, No. 13, 1891.

The manner of separation of the fibres from the parent bundle is at an oblique angle, after which they may be traced for some distance. As they approach the cell the medullary matter gradually decreases in thickness, and the coloring of the fibre is more of a brownish-black than more distally, then, for an exceedingly minute distance beyond, the axis-cylinder alone is seen, and without allowing of a definite view of the actual relation between it and the protoplasmic process, it disappears in the cellular protoplasm. This ending may take place at a considerable distance from the cell body, or quite close to it. In sections in which the cell protoplasm is stained through the incomplete reduction of the chrome salt by the copper acetate, the same relation is seen, only the whole tube is carried into the body of the nerve process without separation of the different parts to the eye.

In the upper portion of the radial band where the fibres are less dense, and sometimes at the sides, the fibres may occasionally be seen to divide into two branches, separating at an obtuse angle (Fig. 3); hence it is to be considered whether one fibre may not be connected with two, or possibly more cells, and the impulses from several cells may not in this way be conducted through the medium of a single fibre to the periphery, or to other parts of the central system.

1, 2, 3, 5, Branching fibres of the intercellular plexus; 4, radial fibre branching in the upper portion of the bundle; 6, 7, anastomosing fibres from the intercellular plexus; 8, collaterals of Ramon y Cajal, separating from the fibre at a T-angle, with a medullary node at each point of departure; 9, 10, end-brushes—9, from the dog; 10, human; 11, star-shaped figure at the point of contact of fine fibres; 12, medullary nodes at the point of departure of branches. Osmium-copper hæmatoxylon stain; Zeiss apochromatic immersion, 1–12, ocular, 4.

From the general direction of the oblique fibres that join the radial band in the inferior cell layers, it is to be surmised that they come or go to the corpus callosum; and by the process of exclusion those that go to others of the pyramidal cells, and form the rectangular portion of the radial bundles, are fibres that pass into the internal capsule, and perhaps go on to the pyramidal tracts.

The fibres composing the entire radial bands in all parts of the outer surface of the brain are medium-sized, non-varicose, medullated fibres, varying but slightly in fineness; if there be any difference it is in favor of the oblique fibres, which have perhaps a slightly larger calibre, and are sometimes irregular in contour. Few collaterals can be seen to come off from the radial bands. The whole arrangement is one similar to the silver broom palm (Thirnax Argentea), the band representing the stem of the plant, the fibres as they come off the side branches, and the cells at the terminations of the tubes the leaves.

Shooting out of the central white masses are numbers of single fibres that pass upward into the cellular layers, where, especially in the so-called fourth and fifth cellular layers, but also in higher regions, they may be seen to end free in close proximity to the smaller cells of these layers. They are fine tubes, regular in contour; all that are to be traced terminate in an end arborization of fine twigs (Figs. 9, 10). The sections having necessarily to be excessively thin, it is not to be determined to what extent they spread out horizontally. At the point where the end brush commences there is always a little node of medullary matter between the first branches, then, as they branch again, a second node occurs, and so on at every division. Almost to the termination they have a blue black stained sheath, that vanishes just before the fine, delicate pointed terminations which extrude from the medullary ends appear. The axis-cylinder, therefore, for an infinitesimal distance is unprotected by any covering, and free to conduct the nerve impulses to the cell body, but there is no continuity of fibril to cell to be observed.

A portion of these singly-entering fibres doubtless belong to the fibræ propriæ of the cortex, but a considerable portion of them must belong to the centripetal-coursing fibres from the periphery.

The Intercellular Net-work.—At the very base of the so-called fifth cellular layer, the horizontally coursing fibres, between the bundles of radial and other fibres coming off from the deeper white masses, show a certain degree of rarefaction; ascending toward the pia the number of fibres in the net-work soon increases greatly, and in the third and lower part of the second layers it is very dense, then higher it rapidly rarefies, until in the upper half of the first cellular layer and lower portion of the barren, the fibres are comparatively scanty. A large portion of those in the first cellular layer go to join the tangential fibres beneath the pial limit at an oblique angle and by single fibres.

The fibres composing the mass of the net-work consist of three varieties, differentiated by their calibre. The coarsest dark-contoured fibres run in all directions, and compared to the second and third varieties form an inconsiderable proportion. They are mainly derived from the subcellular white masses, to which a portion of them may be traced, and to the offshoots of the radial-fibre bands. Occasionally collaterals may be found coming off from their sides (non-radial fibres), invariably at a right angle, with a minute thickening of the medullary sheath at the point of departure (Fig. 8). This thickening is invariable. Where these collaterals end is not often to be discovered, as they are soon lost in mesh-work, or change the angle of their course; rarely they may be traced to end-brushes. These end-brushes are to be found as high as the first cellular layer.

The fibres of the second classification are a little smaller than those of the tangential band, but there is considerable variation in their calibre. They are dark-contoured, and branch in numerous places at an obtuse angle (Figs. 1, 2, 4, 5, 6, 7.). Along their course they have regular swellings of the medullary sheath, and it is invariably from these points that the branching occurs. These medullary nodes have doubtless a definite physiological meaning, as they are constant in perfectly hardened tissues that have been taken from the living animal, and hardened in Flemming's fixation fluid. They probably correspond to the annular constrictions of Ranvier in the peripheral nerves. The branching of these fibres is without doubt. Much more difficult is it to determine positively if they anastomose. In a few instances I have been able to determine this with certainty, two of the examples being given in the figure (Figs. 6 and 7). The fibres occasionally show some difference in their contour, as in No. 1, where the fibre for a short distance centrally is quite fine, then it broadens out considerably and gives off three branches, which are traceable unbranched, but much finer than the parent stem, for some distance.

The third variety is distinguished by the extreme fineness of the tubes, running down to less than one quarter the calibre of the tangential fibres, and with the magnification of a 1 to 12 Zeiss immersion immeasurable. Their medullary matter is quite often clearly defined, an exceedingly thin ring around the finest thread like axis-cylinder. Occasionally there are little varicosities of the medullary substance, and here the axis-cylinder can be also very distinctly seen. The nodes upon them are similar to those of the larger fibres, and when not very deeply dyed by the hæmatoxylon show the fine, darkly stained axis-cylinder passing unbroken through it. Like the larger ones, they branch frequently.

The fibres of the finest calibre are partly derived from those of larger size, partly from an unknown source. Along the margins and crossing the sheaths of the blood-vessels they may be traced for very considerable distances, and then disappear. They may be seen in all portions of the gray cortex, except in the barren and uppermost part of the first layer, where they are either absent or exist in

very inconsiderable numbers Both varieties of fibres show an augmentatiou around the capsules of certain of the cortical cells, and at times the suggestion of a fine spray of nerve-threads may be seen on this capsule, which are apparently non-medullated, but are so fine as to render it a matter of uncertainty. The finest fibres meet here and there in aggregations of six or seven crossing each other, and form a star-shaped figure which has covering the axis a drop of myeline (Fig. 11).

Neither the second nor third class of fibres have any visible connection with the more internal white masses, and run solely in cellular regions with the exception of those going to the tangential band.

The silver method of Golgi has shown that the axis-cylinder processes of the nerve-cells branch in considerable numbers and run in all directions through the cellu lar layers. Therefore it is almost certain that the major part of this net-work is derived from the side twigs of the nerve-extensions of the larger pyramidal cells, as well as from the nerve-processes of those cells (sensitive) that do not leave the gray layers. Unfortunately the osmium-copper-hæmotoxylon method does not stain, except in exceptional instances, the protoplasm of the cell arms; and even when it does, the connection between fibre and protoplasm is lost in the deep coloring. We must accordingly leave the source of the intercellular plexus by this method in some doubt.

In the first cellular layer quite a large number of fibres of about the calibre of the second class ascend obliquely through the layer, some apparently arising in this region, others from deeper parts; all pass directly into the tangential band, where they may be traced for long distances. Branching of these fibres is excessively rare, only in a single instance have I seen it occur. The tangential band is a double one, it not only runs in the transverse diameter of the convolution, but also in the longitudinal. At its fullest development this band occupies rather more than the upper half of the most external layer, but the tubes composing it are at the same time rather widely separated. The further course and termination of the tangential fibres is wholly unknown.

Throughout the whole cortex no non-medullated fibres of any length were found to exist; so far as could be definitely determined, as soon as the protoplasmic character of the nerve cell process is lost, the medullated character of the nerve-fibre begins. It would seem therefore that the axis-cylinder was immediately covered with an isolating envelope as soon as it is separated from the cellular protoplasm.

The fibres from the mass of the larger pyramidal cells are accounted for by the bodies of fibres in the radial fasciæ being almost sufficient to accommodate the whole of them; with the smaller cells it is different, a portion undoubtedly turn upward and run in the tangential fibres to places unknown, but the number of fibres in these subpial longitudinal and transverse bundles are insufficient to take charge of but a small portion, and the remainder must end within the layers of the gray matter itself, among the fibres of the branching and anastomosing plexus, and in single end-brushes; also it is credible that the fibres from many of these cells simply run like certain elements in the molecular layer of the cerebellum, to influence other cells in adjacent portions of the cortex.

These deductions are drawn from the cortex of the human being and of the dog, and apply chiefly to the motor and frontal regions, in particular to the anterior central convolution, though but little difference is to be found in other portions of the cortex of the convexity of the brain beyond some variation in the density of the different fibre bands.

1303 Park Avenue, Baltimore.

Efficient Counter-Irritation.—A physician in Chicago suffers from pruritus ani whenever he takes a glass of champagne. He is a frequent diner-out and is regarded as one of the best after-dinner orators in town.

Clinical Department.

EXTRA DURAL TUMOR OF SPINE; PARAPLEGIA; OPERATION; RECOVERY.

By WILLIAM JONES, M.D.,

Professor of Clinical Surgery University of Oregon, Surgeon to St. Vincent's Hospital, Portland, Ore.

The spine being a new field, but recently invaded by the surgeon, any operation upon it is of importance and should be reported. It adds so much to the mass of knowledge on which must be based surgical interference in the future.

Alice M. W——, married, aged thirty-one, consulted me at St. Vincent's Hospital, on June 5, 1891. She was married seven years ago, and has one child aged six. Five years ago she commenced to suffer with a burning pain below the shoulder-blades. It was more severe on the right side. This pain was aggravated by exercise. Any jar or quick movement caused shooting pains in the same region. Three years ago a deformity of the spine was first noticed. This deformity was an angular curvature of the spine, between the shoulder-blades. There was present well-marked Pott's disease of the spine. The deformity did not apparently increase after first being noticed. She suffered, off and on, with severe pains in the spine and stomach. In August, 1890, she was confined to her bed for a week on account of the severity of the pains. In the following September she commenced to notice some loss of muscular power in the limbs. Her knees would give way when she attempted to step up on a chair. By November 1st, muscular weakness had become so great that she could no longer stand. By December 1st, muscular paralysis was complete from the waist downward. There were involuntary contractions of the limbs. Slight irritation from movements of the bedclothes would cause the limbs to draw up violently. There was complete anæsthesia from the waist downward.

Examination showed a moderate angular curvature of the spine between the shoulder-blades, the most prominent point being the seventh dorsal vertebra. There was complete muscular paralysis from the waist downward. On the right side there was complete anæsthesia from the ninth rib downward, except over the following area: Commencing in the sacral region, with a breadth of one inch, and extending downward, gradually widening to a breath of three inches, on the back of the thigh, just above the knee, where it ended. Within this area she could feel the prick of a pin. All the muscles within the paralyzed area contracted from peripheral irritation. No zone of partial anæsthesia could be determined. Stroking the side of the abdomen caused retraction of the belly. Patellar reflex and ankle clonus were much increased. Tickling the soles of the feet caused flexion of the toes. Tickling the skin of the gluteal region caused dimpling of the ham and contractions about the anus. The above symptoms were not affected by strong extension and counter-extension. All the paralyzed muscles reacted well to the Faradic current.

My diagnosis was pressure on the spinal cord at the ninth dorsal vertebra (the level of complete anæsthesia), or at the seventh dorsal (the apex of the angular curvature).

June 11th.—Dr. Josephi saw her with me in consultation in the capacity of neurologist. He concurred with me in my conclusions, and also that a surgical operation was indicated to relieve the pressure of the spinal cord.

June 12th.—I fitted a turtle shell of plaster of Paris to her back, to be used as a splint after the operation.

June 13th.—Assisted by Drs. Josephi and Bell, and the house staff of the hospital, I operated. After rendering the field of operation, and everything to be used in the operation aseptic, I made an incision on the right side of the spine, extending from the sixth to the tenth dorsal vertebra, and down to the laminæ. I then cut off, with strong bone forceps, the spines of the sixth, seventh,

eighth, and ninth dorsal vertebræ and cleared away the muscles from the arches. The oozing of blood was troublesome, and much time was consumed in stopping it. I removed with rongeurs the laminæ of the ninth and eighth, exposing the dura, which was full and round, but did not pulsate. The body of the seventh was displaced backward about one-fourth inch. At the level of the eighth dorsal the dura was covered by a soft membrane adherent to the vertebra but not to the dura. Its thickness was not sufficient to cause compression of the cord. When the lamina of the eighth was removed the end of the tumor came into view, lying on the cord. The laminæ of the sixth and seventh were then removed. The tumor extended to the fifth, gradually thinning down to the thickness of a membrane. It bulged strongly through the opening in the bones, showing that the pressure was very great. The tumor was loosely connected to the dura below, and was easily separated for about one-half inch, when it became closely adherent. It was soft, and during removal was torn, and a few drops of thick yellow fluid, like that which comes from a degenerated but not inflamed lymphatic gland, oozed from it. This tumor overlaid the cord for an inch and a half, and passed around above to the right side and front of cord. At its thickest part it was the size of the index finger. There was quite a large excavation in the bodies of the vertebræ to accommodate it. The patient's condition at this stage became critical, and the operation was hastily concluded. Four or five cat-gut sutures united the planes of fascia, leaving wide gaps for drainage. Other cat-gut sutures brought the skin together within one-fourth inch. Still other cat-gut sutures were introduced in the skin, and left to be tied at the first dressing.

For forty-eight hours after the operation her condition was critical. Her pulse ranged from 140 to 146, and vomiting was persistent. After this she slowly rallied. The first dressing was delayed till the fourth day on account of her condition. Healing went forward without suppuration and was complete by July 5th.

On the ninth day after the operation there was some indication of returning sensation, especially in the right limb. On the twenty-first day she could feel a pin prick everywhere on the right side. On the left side sensation had returned on the back and sides of the thigh, and on the back of the leg to a few inches above the knee.

July 6th.—She went home to Eastern Oregon, promising to send me reports from time to time.

August 6th.—She reported by letter that sensation had returned everywhere, and that she could move the big toe and the one next to it on the right foot, and the big toe on the left foot. The reflex contractions continued vigorous.

October 12th.—She could lift the left foot from the floor, the right one could not be moved so well. She said that her condition would remain unchanged for four or five weeks and then improvement would be rapid for a few days, when matters would again remain stationary.

December 8th.—She could stand alone and could run a sewing-machine. January 5, 1892, her husband reported to me in person that sensation was perfect everywhere, that she walked about the house freely on crutches, and that her general health was excellent. She had within a few days improved greatly.

The tumor was never examined microscopically, but was probably tubercular. It sprung from the diseased vertebræ. The sixth, seventh, and eighth dorsal vertebræ were anchylosed, and the body of the seventh in particular was to a great extent absorbed. No carious bone was discovered.

This case shows that the functions of the cord can be restored after having been suspended for a long time by pressure. For more than six months paralysis of motion had been complete below the lesion. It shows, too, that improvement is very slow and progresses for a long time. Seven months have passed since the operation and improvement still goes on. The line of anæsthesia did not truly indicate the level of the lesion. Pressure was very great at the sixth dorsal, yet sensation was unimpaired down to the ninth.

A CASE OF HYPERTROPHIC SCIRRHOSIS OF THE LIVER.

By J. JOSEPH KINDRED, M.D.,

FIRST ASSISTANT-PHYSICIAN AT THE PENNSYLVANIA STATE LUNATIC HOSPITAL, HARRISBURG.

An interesting case of this rather rare disease, accompanied by scirrhosis (atrophic) of the kidneys and fatty degeneration of the heart, came under my observation recently, the chief features of which I submit.

Whether the case to be presented should be considered as one of those rare conditions of alcoholic scirrhosis where the liver remained greatly hypertrophied throughout the course of the disease, or whether it should be more properly considered as "cirrhose hypertrophique avec ictère," described by the French writers as having quite a distinct pathology, was not, after a careful examination of the pathological appearances of the organ, fully determined. The clinical course of the disease, however, certainly belonged more to the latter disease than to ordinary scirrhosis of the liver, as will be seen from the following:

J. W. B——, aged fifty-one; a druggist; married; no history of syphilis; had indulged steadily in alcoholic excesses, but not for fifteen years prior to the appearance of the first symptoms of the disease. About three and a half years previous to the patient's death, the first indications of hepatic trouble were observed. At this time an enlargement in the hepatic area, coincident with jaundice and slight derangement of the digestive tract was noticed. The enlargement increased rather rapidly, examination from time to time showing dulness over the greater portion of the abdomen with the exception of the left iliac region.

No roughened surface, but a large, smooth-feeling tumor, extending uniformly over the abdomen, was revealed by repeated palpation.

The spleen was found enlarged, and greatly so just before death.

Involvement of the kidneys being suspected also, the urine was examined and albumin found in large quantities.

There was not at any time in the course of the disease evidence of ascitic effusion, which would naturally be looked for in ordinary scirrhosis. The icterus was not marked for some time previous to death.

Anæmia, languor, weakness, derangements of the digestive tract, and the usual nervous symptoms became more and more troublesome, and the patient finally succumbed three years and a half after the initial symptoms appeared.

The clinical points here suggesting the differential diagnosis of hypertrophic scirrhosis from the ordinary scirrhosis of Laennec, were the more or less marked persistence of the icterus throughout the greater part of the disease, the great enlargement of the spleen, and the absence of ascitic effusion from the first to the last; while the even surface and uniform enlargement of the organ excluded enlargement due to echinococcus, carcinoma, and other new growths.

It will thus be seen that the whole clinical history was, as has been stated, in accord with that of "cirrhose hypertrophique avec ictère," but that the pathological findings of the following post-mortem examination did not decide that the disease had not been at some previous transitional stage of its pathology the ordinary alcoholic scirrhosis.

The liver was found to occupy the greater part of the abdominal cavity, and to press upward about three inches above its normal level and against surrounding viscera. Its weight was seven and one-half pounds. It was some-

what glistening in appearance, quite smooth as to its surface and unusually firm in consistency, giving on section a sensation of cutting through cartilage.

The gall-bladder was quite small and contained very little bile, that being thickened or inspissated.

The cut surfaces showed little yellowish areas of liver parenchyma, between which were masses of connective tissue, which on being more minutely examined showed that the bands of connective tissue were quite uniformly distributed, and that the lobular markings were here and there indistinct. There was found no evidence to sustain the rather hypothetical claim that this form of scirrhosis begins as an inflammation of the interlobular bile-ducts and extends to the surrounding connective tissue.

The spleen was more than twice its normal size, brittle, and extremely congested, appearing as if it had been the seat of recent capillary hemorrhage.

The kidneys were in the pathological state known as small granular kidney or renal scirrhosis.

The heart was quite small, and far advanced in fatty degeneration, with the right ventricle dilated and flabby.

A CASE OF ANOSMIA.

By E. SCHALCK, M.D.,

NEW YORK.

Cases of anosmia, pure and simple, without any visible external changes, are extremely rare; most of those which have been recorded were congenital and were due to the non-development of the olfactory nerves. Bonet[1] and Pressat,[2] at the beginning of this century, reported cases of this sort. Later on in literature Holm[3] mentions two cases of syphilis in which there could be found no pathological change in the nose, and in which the existing anosmia was attributed to changes in the cranium and meninges. There was a case reported by René[4] in which a blow upon the nose caused complete loss of smell, the sense of taste not being impaired. Mackenzie[5] mentions also a pure case of anosmia. A physician was thrown out of his buggy and the fall stunned him. Having regained consciousness, he discovered that he had lost his sense of smell. Some cases of similar nature were reported by Notta.[6]

All others, so far reported, were not pure. They were either unilateral, or combined with paralysis of the facial nerve. Optic neuritis, polypi, tumor of the brain, caries at the base of the cranium, and hysteria, are generally complicating or causing the disease.

I shall now mention a case which came under my observation, and which serves to illustrate plainly the mechanism of an injury that resulted in anosmia. Mr. K——, thirty-eight years of age, a carpenter by trade, one night on coming home fell downstairs. Toward morning he was found unconscious, lying at the foot of the stairs. When I saw him in the morning, he was still in a somnolent condition. There was profuse perspiration, the temperature was normal, pulse slow, respiration distinctly lessened and of a Cheyne-Stokes character. Pupils, of equal size, reacted normally. There had been some oozing of blood from the mouth, but not from nose or ears. Loud calling aroused him so that he would open his eyes, but he would instantly fall back in his former condition. In the region of the occipital protuberance there was a scalp wound about two inches in length, which subsequently healed by primary union. This condition of semi-coma lasted about forty-eight hours, when he suddenly awoke without recollecting anything of what had happened.

Total anosmia was the permanent result of this fall; his sense of taste was not impaired, and there was and is not now any paræsthesia or anæsthesia of any kind. This case illustrates very well the action of contre coup. There were present all the symptoms of concussion of the brain, not those of fracture of the skull. The original point of injury was the occipital protuberance, the point where it showed its deleterious effects exactly opposite, that is, in the olfactory nerves.

It is probably of interest to know how this anosmia manifested itself. The patient did not complain first of his loss of smell, of which he was unaware, but of a loss of appetite; everything seemed to him to taste alike, and he could not enjoy his meals. I must yet mention that this anosmia has remained unchanged for many months up to date.

Too little attention is paid to the hygienic reports of this affection. A man without the sense of smell, in our era of gaslight, is in constant danger of losing his life, for it is only by this sense that he is warned of the presence of many deadly gases in the atmosphere.

Also, an already existing form of disease can be influenced by anosmia in a high degree. All patients suffering from anosmia complain of loss of appetite, and of what consequence this condition, in a case of tuberculosis or other constitutional disease, wherein the feeding of the patient is of such importance, may be, every physician knows. Two further cases of anosmia are instructive in this regard, although etiologically offering nothing particular, as one was due to polypi of the nose and the other to atrophy of the turbinated bones. The first case was that of a man, forty years of age, who suffered from anosmia for seven years. He only complained of loss of appetite, which after removal of a number of polypi returned, and he gained considerably in weight in a few weeks. The second case was that of a woman, thirty-six years of age, of tubercular diathesis, with a pleuritic exudate in the right pleura, who showed marked improvement after her atrophic rhinitis, of which she also suffered, was treated and her sense of smell had been restored.

COMPLETE ABSENCE OF URETHRA; OPERATION AND CURE.

By C. H. VOORHIES, M.D.,

WICHITA FALLS, TEX.

Mrs. L——, married, gave birth to a male child on October 9, 1891. The child was to all appearance healthy, robust, and perfectly formed. Thirteen hours after birth it was discovered by the nurse that the child had passed no urine. The father was immediately sent after the doctor, who upon examination found the child had a malformed penis with no opening to the bladder. The doctor and nurse attempted an operation, but failed. I was immediately sent for, and assisted Dr. Burnside in making one. A tenotome was used, which, beginning at the meatus, was directed downward and inward to a point beyond where the ejaculatory ducts should open into the urethra, before we struck any canal. We then passed a probe through the opening into the bladder, and relieved the little one of the accumulated urine. For several days afterward the small probe was passed, and soon the child was able to void its urine alone, and is now a stout, fat, and well-developed baby.

The child's penis at birth presented the appearance of one who had been circumcised or operated upon for phimosis. It was about one inch in length; the foreskin drawn back and notched upon the top. The glands and testicles were well formed and healthy in appearance.

The question now presents itself, Will this child (when grown to manhood) be able to beget children? Will nature restore the opening of the ejaculatory ducts into the canal made by human hands?

If any of the readers of this article have seen such a case as this, I would be glad to have them communicate with me, as I have been unable to find such a one on record.

Progress of Medical Science.

Onanism Cured by Hypnotic Suggestion.—Dr. Bernheimer (*Revue de l'Hypnotisme*) relates an instance of cure of the habit of onanism, after the first *séance*, in a boy eight years of age, who had practised the vice for three years, and at the time hypnotic treatment was instituted admitted that he gave way to his desires as often as three or four times each night and two or three times a day. All other treatment, such as bromide of camphor, bromide of potassium, restraining apparatus, baths, special diet, intimidation, threats, etc., had failed. Suggestion during hypnotic sleep was repeated daily for a fortnight, the suggestion being that he would never again have an idea of touching himself either by day or during sleep at night, and that he would, henceforth, be strong enough to resist all temptation. From the first day there was marked general improvement, gain in weight, and entire freedom from the habit. Suggestion does not consist in an order not to do a thing, but in the confidence given to the child. It is the idea put into his brain that he would no longer succumb to the impulse.

Anuria of Scarlatinal Nephritis.—Dr. Starr recommends the following mixture:

℞. Ext. jaborandi fld ..... 15 gm.
Potass. citrat ..... 25 "
Aquæ dest ..... 75 "
M. Sig.: Teaspoonful every four hours.

Acute Gonorrhœal Cystitis.—Dr. Wickham recommends oil of sandal-wood in acute cystitis of blennorrhœal origin, giving sixteen capsules in the twenty-four hours, each containing about six drops (forty ctgr.) of the fluid. This also has a very beneficial action on hæmaturia. Other balsamics have been found only to irritate and aggravate the symptoms in gonorrhœal cystitis. The action upon the mucous membrane of the stomach is a stimulating one, which permits of suitable diet. Horteloup is given credit for the method, which usually renders instillations of nitrate of silver uncalled for.—*Union Médicale*, No. 145, 1891.

Inoculation of Chancroid.—Dr. Coignet formulates the following practical rules: The pricked point should be small and superficial, so as to avoid as much as possible implication of the deep skin. It should be as far away from the genital region as possible. If by the day after inoculation there is not the least inflammatory areola, you can say at once that nothing will come of it. If there is a slight inflammatory zone, it is impossible to say till perhaps some days have elapsed. If, however, by the day after inoculation there is a well-formed pustule, with greatly inflamed peripheric zone, the result can be put down as positive. In this case it is useless to wait longer and the ulceration should be destroyed at once, before it has a chance to spread.—*Lyon Médical.*

Identity of Variola and Vaccinia.—Dr. Fischer inoculated two calves with the pus from small-pox, obtaining in each instance typical symptoms of cow-pox. The lymph from those calves was passed through twelve others, and a part of it through three others, and was then used for vaccinating children. Normal and mild vaccinia followed in all those who had not previously been vaccinated.—*Fortschritte der Medicin*, ix., 13.

Phosphorus in Rachitis.—Mettenheimer proposes the following formula, which he considers superior to that of Kassowitz (phosphorus, one ctgr. in one hundred gm. of almond oil):

℞. Phosphorus ..... 0.01 ctgr.
Ol. amygd. dulc ..... 0.30 gm.
Pulv. sacch. alb.,
Pulv. gummi arab. ..... āā 0.15 gm.
Aq. dest ..... 0.40 gm.
M. Sig.: Teaspoonful at dose.

—*Nouveaux Remèdes.*

Antigalactagogue Action of Antipyrin.—Guibert has found that the lacteal secretion can be completely suppressed in from two to six days by antipyrin in daily dose of thirty grains or more, given in divided portions every two hours. After thus employing antipyrin in nineteen cases, it is regarded as harmless and of real service, where it is desired to suppress the milk secretion.—*Le Practicien.*

Thilanine is a lanolin derivative which Siebels has obtained by acting upon lanolin with sulphur. This chemical compound contains three per cent. of sulphur. It has been employed by Dr. Saalfeld in several varieties of skin disease, and has been found devoid of irritating effect, and is useful in moist eczema, sycosis, acne, rosacea, etc. —*La Semaine Médicale.*

Influenza Colds.—Few remedies are more reliable, and act better as a preventive, or lessen the distressing symptoms of an influenza cold, than the following mixture:

℞. Sodii salicylas. ..... ʒ jss.
Liq. ammon. acet. ..... ʒ ij.
Aq. camph. ..... ad ʒ vj.
M. Capt.: ʒ ss. omnis 3tiis horis.

If this be taken every two or three hours when the first symptoms of cold come on, it will usually ward off the attack.—*British and Colonial Druggist.*

Acute Oöphoritis Complicating Pregnaney.—Dr. Coe, writing on this subject in the *American Gynecological Journal*, December, 1891, gives several instances of such complication and says: "In a patient with a history of previous acute oöphoritis and peri-oöphoritis, whether occurring before or during pregnancy, apprehension must be felt as to the possibility of a recurrence of the former inflammation after delivery. Labor should be conducted with rigid aseptic precautions, and with the least possible amount of interference; rough manipulation of the fundus uteri, as in expression of the placenta, is especially to be avoided."

Permanganate of Potash has been found by Dr. Bokai to be the best antidote for phosphorus poisoning. A solution containing from two to five parts to the thousand is said to be well tolerated by the stomach.—*Gaz. Méd. de Liège.*

Treatment of Scabies.—Kaposi recommends the following plan of treatment, which has been successfully carried out for ten years in the Vienna Clinic, in about five hundred patients each year:

℞. Florum sulph.,
Ol. fagi. ..... āā 20.0
Sap. vir.,
Axung. porci. ..... āā 40.0
Cret. alb. pulv. 5.0
M. Sig.: Apply once without previous bath and wrap patient in woollen blanket.

In private practice the patient can put on a suit of tight-fitting woollen underwear and go about. Wool has the advantage over linen that it does not soak up the ointment, but leaves it in contact with the body. A bath is to be taken only after the skin has begun to peel. A bath before the ointment makes the skin unnecessarily liable to irritation.—*Deutsche Medizinische Zeitung.*

Temperance and the Longevity of Clergymen.—It is satisfactory to know, on the authority of Dr. Drysdale, that the mortality of the clergy of the Established Church of England has fallen greatly since the spread of the temperance movement among them. Whereas between 1861 and 1871 the mortality of the clergy between the ages of twenty-five and forty-five was 5.96 per 1,000, it fell between 1880–82 to 4.64 per 1,000. The question may be raised whether this apparent lessened mortality among clergymen may not be evidence of the universal fall in the death-rate during recent years, of which the apostles of sanitation claim the credit.—*Hospital Gazette.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, March 12, 1892.

THE SEQUELÆ OF INFLUENZA.

Now that we have passed through three winters of *la grippe* we are in a position to formulate some ideas as to the more remote effects for which the disease can be held accountable.

It would appear from contemporary literature that no organ of the body is exempt from the possible after-effects of an attack of influenza, and while there is undoubtedly a tendency to attribute any unusual symptom showing itself in a patient who has suffered from the epidemic disease to its influence, still there have been observed sufficient well-defined sequelæ to make an interesting and instructive chapter. Althaus thinks that the *materies morbi* of influenza resembles that of syphilis in its effects upon the nervous system after the actual attack is over. Sansom has also found that it is especially upon the nervous system that the virus of influenza acts, and, in an article appearing in the *Lancet* of January 2d, treats at some length of the various painful affections which he has found to follow an attack of the grip. In his cases the pains were localized chiefly in the epigastrium, head, region of heart, and extremities. The attacks were frequently nocturnal and often very severe. Several instances simulated angina pectoris, one patient described his pain as a "grip" or "screw" at the heart. Dyspnœa also occurred independently of exertion. Aching in the arms, calves, thighs, etc., chiefly at night, was frequently complained of.

In regard to the visceral neuralgia, there are signs of localization and, in some instances, of local tenderness that point to a local cause, and it seems probable to the writer that in some such the sympathetic fibres and ganglia are alone affected. In other cases there seems to exist a form of neuritis analogous to that caused by many other toxines. The conclusion reached is that these remote consequences of influenza are due to the proximate cause of a peripheral neuritis affecting the sympathetic ganglia and nerves, the vagus, and the sensori-motor nerve trunks.

In an excellent article on the nervous and mental phenomena of influenza by Dr. Mills, published in the *Medical News*, January 30, 1892, neurasthenia due in part to cardiac weakness is mentioned as one of the after-effects frequently noted. The cases are distinctly of the melancholic type, no ordinary amount of work can be endured, and the subjects are weak, worrisome, and unrecuperative. The order of frequency of organic nervous diseases left in the wake of the epidemic as observed by this author is: neuritis, meningitis, myelitis, and cerebritis. Almost every variety of neuritis has been observed, and multiple neuritis while not common has not been rare. Isolated neuritis of almost every cranial nerve has been recorded, with resulting optic atrophy, loss of smell and taste, ophthalmoplegias, oculo-motor, facial, and bulbar or pseudo-bulbor palsies.

"Distinctively neuralgic pains," the author says, "are probably due to toxæmically depressed or exhausted sensory nerve-roots or centres in the cord and bulb."

One striking example of bulbar paralysis was seen. Meningitis is comparatively rare, and reports of cases can be accepted only when confirmed by autopsy or made by reliable observers. Persistent pain in the head, often diagnosed chronic meningitis, the author believes to be more generally neurotic than meningeal. Convulsions, hystero epilepsy, chronic torticollis and facial paralysis are other nervous manifestations observed.

The subject of insanity following influenza has been widely discussed. Lelady believes the rôle of influenza in its causation may be predisposing or exciting, but in all cases there must be acquired or inherited predisposition. The onset is often sudden; cure depends rather on general conditions and there is no special indication in treatment. The commonest type is stated by Mills to be a form of melancholia not infrequently assuming the form of melancholia agitata. "The patients are intensely depressed and emotional; they are filled with apprehensions of disgrace and ruin, they are suspicious and delusional with reference to those surrounding them; they are frequently unwilling to eat, or to rest, or to take medicine, and in some cases they have definite delusions of terrible character, for the most part hypochondriac or religious. They are frequently plagued with the thought of suicide, and sometimes make suicidal attempts."

One of the most frequent complications, according to the report of Dr. Krannhals on the epidemic in Riga, is otitis media. Out of seventy-three ear affections following an attack, fifteen were of catarrhal otitis media, and thirty-eight purulent. Autopsies were made on five cases of purulent meningitis which were neither of tubercular nor traumatic nature, and among the rare complications are recorded four instances of abscess of the liver.

Jansen observed over a hundred cases of otitis at the university clinic in Berlin. No perforation occurred in one-seventh of the cases. Twice the mastoid process was affected. Gangrene of the foot has been reported by Johannsen in a patient fifty-two years of age, and severe phlegmasia alba dolens in a girl of fifteen, both as the result of influenza.

Gottschalk has noted the frequency of endometritis associated with free hemorrhage and he thinks the influenza virus may directly attack the pelvic connective tissue. These are by no means all the complications and sequelæ which have been thought to belong to the influenza, still they serve to keep us reminded that with the wane of the epidemic we may encounter conditions not readily explained until we go back in the history to the time of the acute attacks.

THE MODE OF ACTION OF GUAIACOL IN TUBERCULOSIS.

Although many writers are in accord concerning the benefit to be derived from the use of guaiacol in tuberculosis, there is a very evident want of agreement as to the manner in which this favorable effect is produced. While some have thought that the drug possesses a true specific action, destroying the tubercle bacilli in the tissues just as it does in test-tube cultures, others have maintained that it is nothing more than a good tonic, stimulating the secretion of gastric juice, and thereby aiding digestion and promoting more perfect nutrition. This second hypothesis can hardly be maintained, however, since guaiacol carbonate, which is said to act equally as well as the uncombined drug, is non-irritating and tasteless, and probably passes unchanged through the stomach without exciting any increased secretion of the gastric juice. The first supposition is equally untenable, according to Drs. Hölscher and Seifert, who have found (*Berliner klinische Wochenschrift*, January 18, 1892) that guaiacol does not circulate as such in the blood, but that it forms a new combination, the exact nature of which has not hitherto been well understood, which exerts no poisonous effect whatever upon the tubercle bacillus. How, then, is the beneficial therapeutic action of the drug in tuberculosis brought about?

As we have just said, Drs. Hölscher and Seifert have shown that guaiacol was found in the blood in a state of combination. Now the albuminoids are, of all the constituents of the blood, the most prone to enter into combination with foreign substances, and as guaiacol is excreted in the form of a sulphate, they concluded that the drug combines with the blood-serum by means of the sulphur which the latter contains. But the blood of a phthisical person contains, besides the normal albuminoids, others formed through the agency of the bacilli. These latter albuminoids are very unstable and are prone to undergo chemical change whereby they became poisonous. It is the presence of these toxic albuminoids that gives rise to the constitutional symptoms of tuberculosis, anorexia, fever, night-sweats, etc. But they are much less stable than the normal albuminoids and combine more readily with guaiacol and certain other substances introduced into the circulation, forming with them harmless compounds. Thus it is, they hold, that an amelioration of the general condition follows as promptly upon the administration of this drug in the case of pulmonary tuberculosis. The guaiacol does not act upon the bacilli at all, but simply renders harmless the toxines elaborated by them. The local pulmonary process is not influenced directly by the drug, but the constitutional disturbance is removed, the fever subsides, the night-sweats cease, the appetite returns, the digestion is improved, and health is restored. Thus the organism is strengthened and is enabled to cope successfully with the bacillary invasion if the latter be not already too far advanced.

The greater the amount of the remedy which is introduced into the system, the more completely are the toxines destroyed, hence large doses are advisable. And as the authors have shown in a previous communication that guaiacol carbonate is better tolerated than the pure drug, it is this form that they recommend for administration in the treatment of pulmonary tuberculosis.

It is very probable that this is the way we shall ever be forced to contend against this and many other forms of bacillary disease. The attempt to destroy the microorganism by poisons introduced into the system must be futile, from the impossibility of introducing an effective amount without prejudice to the life of the individual. But by rendering the bacillary products innocuous we can lighten the labors of the organism, free it from the crippling effects of these toxines, and so leave it free to contest with and overcome the bacilli. That the healthy organism can in most cases do this successfully is a matter of every-day experience, otherwise men were extinct ages ago.

ADVANCES IN PHYSIOLOGICAL CHEMISTRY.

The progress of physiology and physiological chemistry gives every now and then a sharp turn to our methods of viewing and treating disease. Thus, for example, in times past the profession has starved fevers, then it has fed fevers, now it is inclined to water them.

Perhaps in no direction have medical views changed more than in regard to the dieting and feeding of the sick and to the medication of nutritional disorders. For two decades a vast deal of attention has been paid to the subject of making things easy for the stomach. Pepsin, ptyalin, trysin, peptones, peptonic pills, digested and half digested milk and beef have been prescribed in enormous amounts, and no doubt with some benefit.

But there is a possibility that too much of this sort of thing is done, and that much of the supposed help to digestion given by prepared foods is fanciful. It has been demonstrated beyond any doubt that albumin is absorbed from the rectum and stomach without first being changed into peptone. It is known that the peptones must be changed into serum-albumin before they enter the blood, and finally there is good ground for believing that all the proteid matter which is used in the building up and repair of tissues comes from albumins which escape being converted into peptone in the alimentary tract. Peptone supplies force, unchanged proteids supply tissue.

A good deal of medication has been based on the supposed fact that the secretions of the intestinal tract are alkaline. The studies of Macfayden, Woricki, and Sieber show that this is not entirely true, for the secretion, as found in the lower part of the small intestine, is uniformly acid.

A very important and dominant idea in practical medicine is that the tissue changes of nutrition and function are chiefly oxydations. Hence we insist on fresh air, exercise, and abundant supplies of oxygen. But it is known that synthetic processes also occur in the processes of digestion and absorption as well as in tissue-making. In digestion, for example, hydration is an important factor, and in the absorption of fats there is a synthesis of fatty acids and glycerine, so that as a result neutral fats alone enter the lymph. The investigations of chemists have also shown that the liver-cells do synthetical or constructive as well as oxydizing work. The old view of Liebig, that our bodies are mainly furnaces, is not, therefore, strictly true, and we are learning to-day that rest is as

important as exercise in securing improvement in nutritive functions.

These views, which are in part suggested by an able address of Dr. V. C. Vaughn, of recent progress in physiological chemistry, show that certainty has not yet been reached in our knowledge of diet, digestion, and nutrition, and that the modern physician must keep ever alert to the progress made in the physiology and chemistry of the human body.

REGULATING PRESCRIPTION PADS.

The present legislature of New York promises to do some very remarkable things, but nothing could be much more astounding than the project recently inaugurated by Assemblyman Walter G. Byrne, of this city. The statesman in question has introduced a bill proposing to make it compulsory for physicians to use for their prescriptions blank forms to be supplied by the health authorities. These blanks are to have stubs upon which the physician must write a copy of his prescription. The regulation is to apply, for some reason, only to persons practising medicine, surgery, and dentistry in cities of over one hundred and fifty thousand inhabitants.

The objects of the bill are, we take it, to prevent mistakes in prescription-writing and prevent prescribing by others than licensed medical men. Such objects are undoubtedly laudable, but the plan devised is unjust, unreasonable, burdensome, and impracticable to the point of ludicrousness. We do not see why a physician practising in a town of 50,000 inhabitants is not just as liable as any one else to require the official blanks.

In case of an emergency, when, as might often happen, the doctor had no prescription pad, the results would be most serious.

Apart from this it is manifestly impossible for the law to be enforced, without a systematic inspection of all drug stores. Even then the law could and would be evaded in many ways. If any law so monstrous were really enacted, probably the first result would be to make physicians deal out their own drugs. This would be disastrous to the drug business, inconvenient to physicians, and often harmful to patients.

In fact, the proposed law is in every way so absurd and obnoxious that it seems impossible that it should be considered seriously.

Yet, when legislatures pass laws regulating physicians' fees, forbidding intoxication, and putting various other paternal limitations on personal liberty, it is difficult to know what to expect. We trust that our State Medical Society will look after Statesman Byrne.

MARRIAGE AND THE TRIPPER FADEN.

No pathogenic germ has given rise to more discussion than that of gonorrhœa. It is at present still denied by many genito-urinary specialists that it is always present in specific urethritis or is always the cause of the disease. There is still greater doubt and uncertainty as to the contagiousness of chronic urethral discharges. On the whole there seems to be a tendency to adopt in a measure the view promulgated many years ago by Noeggerath, that many of the pelvic troubles of women were caused by them. Sänger states that about one-ninth of all gynecological diseases are the result of gonorrhœal infection. Finger asserts, regarding marriage, that it should be absolutely prohibited in all cases where the existence of a chronic urethritis is evidenced by the presence of the "morning drop" or tripper faden in the urine, until the following facts have been established:

1st. That after from two to four weeks of daily observation, the secretions from the urethra are found to be free from pus and made up wholly of epithelial cells.

2d. That no gonococci can be detected by the microscope, even after a purulent discharge has been established by the employment of irritating injections of corrosive sublimate or nitrate of silver; and,

3d. That neither prostatitis nor stricture exists.

In an article on this subject by Dr. George E. Brewer (*Journal of Cutaneous and Genito Urinary Diseases*) much the same doctrine is advocated. Dr. Brewer cites the case of a young man who had had an attack of gonorrhœa six years previous, and who for three years had had no urethral discharge. On examination of the urine, however, the tripper faden were found, and in these gonococci were seen. Against medical advice the patient married and his wife speedily developed a severe gonorrhœa. The possibility of a recent infection of the man was excluded. The case is rare, but is not an isolated one, and it seems to show that a person who has tripper faden containing gonococci should not marry until the morbid condition is relieved.

CONDITIONS OF CURE IN CONSUMPTION.

In a paper read at the Medical Society of London by Dr. Yeo and published in the *British Medical Journal*, January 16, 1892. The author in discussing the conditions under which phthisis is curable, stated that only a few weeks before Koch's announcement of his discovery, he had made the remark in one of the London Medical Societies that if a perfectly certain cure for tuberculosis were at any moment to be discovered it would leave the majority of the then existing cases of consumption incurable, because the conditions of cure no longer exist. In other words, if we are able to heat the patient before his pulmonary tuberculosis has developed into phthisis, we may hope to contribute to bringing about the same arrest and cure as is at times found in the post-mortem examination to have taken place perhaps spontaneously.

All of our efforts, the author says, should be directed to the diagnosis of the "occult stage" or stage of "germination," and he considers a diagnosis possible to the extent of probability while not to the extent of certainty. As regards the clinical recognition of this early condition, Professor Grancher is quoted in the following words:

"In an individual, suspected or not of tuberculosis, a few tubercles begin to develop slowly; embryonic cells and giant cells form and group themselves together, so as to constitute the follicular tubercle—that process lasts a long time and is silent—and nothing appears changed in the health of the man doomed to phthisis; sometimes a little anæmia, a little debility, a slight cough, a little quickened respiration—nothing more."

The author is disposed to consider the early occurrence of hæmoptysis as a condition favorable to the cure of

phthisis because it calls attention to an early stage which might otherwise pass unobserved.

Another condition favorable to cure is the absence of marked hereditary predisposition in accidental infection of robust individuals. A mitigated virulence of the bacillary infecting agent is looked upon as another possible influencing condition, as also a small number of bacilli originally gaining access to the lungs and the channels through which this access is accomplished.

A most essential condition of cure is that of a "sound organic state and a sustained functional activity of the organs of digestion and assimilation. Food should be given in such form as to insure methodic alimentation and indeed hypernutrition.

A dry aseptic atmosphere especially favors the arrest of pulmonary tuberculosis, but the cold Sanatoria in the Swiss Alps the author has found by no means always unirritating. Life in the open air of country or sea with continuous and strict attention to the minute details of daily life are conditions not to be neglected.

Repeated and continuous counter-irritation, antiseptic inhalations, and the internal use of such antiseptics as creosote or guaiacol, are recommended, but that any remedy may cure or contribute to the cure the conditions which make a cure possible must exist.

News of the Week.

Dr. Lewis A. Sayre's Birthday occurred on February 29th, and consequently he has but one every four years. Now that the secret is out, we are not surprised that he is still so young, alert, and full of ardor. Many happy returns. All of his numerous friends, here and abroad, will join with the rector of Grace Church in tendering him their best wishes as expressed in the following charming sentiment:

"Grace Church Rectory,
"New York, February 29, 1892.

"Dear Dr. Sayre:

"And is it true,
That Nature set her clock for you
Some four-and-fifty years too slow?
How clever of her to foreknow
That you would keep yourself so young,
So firm of heart, so sound of lung,
That she would never be detected,
Nor you so much as once suspected
Of being older by a day
Than leap-year records seem to say!
Eighteen, dear friend, or seventy-two,
Which 'ere it be, good luck to you.

"William R. Huntington."

St. John's Guild.—The twenty-fifth annual report of this association has been published. During the past summer the floating hospital made five trips a week from July 1st to September 3d, or thirty-two in all, four having been omitted on account of stormy weather. On those trips a total of 28,664 children and mothers were carried, at a cost of a little over twenty-six cents each. The seaside hospital on Staten Island was open from July 8th to September 3d, during which time 1,067 patients were received, of which number 384 were mothers and 683 children. The cost of caring for these averaged $3.37½ each per week. The Guild is in need of funds for the continuance of its work the coming summer, and also for the support of the children's hospitals throughout the year. The work of the Guild in saving the lives of children during the heated summer term is most real, and cannot be too highly commended, and it is deserving of liberal support and encouragement.

French Congress of Surgery.—The Surgical Congress of 1892 will be opened in Paris, at the Faculty of Medicine, on Monday, April 18th, under the presidency of Professor Demons, of Bordeaux. The first sitting will be held at 9 A.M., and is to be devoted to the discussion of general questions, but the formal inauguration of the Congress will take place at 2 P.M. The following questions have been placed on the agenda for discussion: 1, The pathology and treatment of surgical gangrene; 2, the pathology of infectious complications in the surgery of the urinary organs; and 3, surgical operations on the biliary passages, with their immediate and remote results. The morning session will be devoted to general discussion.

Investigating the Keeley "Cure."—New York State has refused to undertake to investigate the Keeley Institute, which has been established in a neighboring county. This is a sensible act. On the old principle of giving the calf enough rope, we believe that the 'Institute" will work out its own end.

The Medical Society of the Missouri Valley will hold its next annual meeting in Leavenworth, Kan., March 17th and 18th next. The titles of papers to be read should have been sent to the Secretary, Dr. F. S. Thomas, before March 1st. The fee for this meeting is $2.

The Tennessee State Medical Society will hold its annual session for 1892 in Knoxville, beginning April 12th—the second Tuesday of that month. The Secretary, Dr. D. E. Nelson, of Chattanooga, Tenn., will furnish additional information on application. An excellent session is anticipated.

The Executioner of England, who has hung two hundred criminals in his day, has resigned and is going on a lecturing tour. He will advocate the abolition of capital punishment.

New Buildings for the Jefferson Medical College of Philadelphia.—The Board of Trustees and the Faculty of the Jefferson Medical College have just completed the purchase of two large lots on Broad Street, giving them a frontage of about three hundred feet and a depth of one hundred and fifty feet, upon which they will proceed to erect at once a handsome hospital, lecture-hall, and laboratory building. The estimated cost of the buildings is $500,000.

The New York Pasteur Institute.—Dr. Paul Gibier, of the New York Pasteur Institute, states that he contemplates closing the Institute, because, instead of receiving encouragement, he had been cheated out of the money he had earned.

The Function of the Supra-renal Bodies.—According to MM. Langlois and Abelons, who, at a recent meeting of the Biological Society, brought forward the results of

their further researches on the function of these physiologically little known organs, the destruction of one supra-renal body does not entail death, while the removal of both invariably does, accompanied by all the phenomena described by Brown Séquard, paralysis of the respiratory muscles, etc. This paralysis they found to affect the terminal nerve-plates in the muscles. At the moment of death, and a little before, the sciatic and phrenic are absolutely inexcitable, although the muscles supplied by these nerves in part respond to stimulation. The blood of guinea pigs on which the observations were made caused, when injected under the skin of the frog, phenomena analogous to curarization, and MM. Langlois and Abelons incline to the belief that a chief function of the supra-renal capsules is to destroy or neutralize some such poisonous substance engendered by the organism.—*British Medical Journal.*

The Kansas State Medical Society will meet in Fort Scott, May 3, 1892.

The Deaf Veterans.—There are 5,389 deaf soldiers on the pension list, and of these 1,260 are totally deaf. For total deafness a pension of $30 a month is granted, and for deafness approximating total, $27. This is not considered enough, by the veterans.

A Bill to Prevent Public Demonstrations of Hypnotism.—The following bill has been drafted by the Buffalo *Enquirer* and presented to the State Legislature:

An act to prohibit public exhibition of hypnotic experiments and to prohibit hypnotic treatment by anyone except duly licensed physicians.

The people of the State of New York represented in Senate and Assembly do enact as follows:

Section 1. It shall be unlawful for any person except duly licensed physicians, in the course of lectures to medical students or before scientific bodies, to give exhibitions of or perform hypnotic demonstrations in public.

Section 2. It shall be unlawful for any person not a duly licensed physician to hypnotize another.

Section 3. Any person violating either of the foregoing provisions of this act shall be guilty of a misdemeanor.

Section 4. This act shall take effect immediately.

New Journals.—*The National Medical Review* is the name of a new monthly published at Washington, D. C., and edited by Dr. Charles H. Stowell. It is for the busy practitioner, and is all written by the editor. The *Hot Springs Medical Journal* is also a monthly, edited by Drs. J. M. Keller, S. W. Franklin, Thomas E. Holland, and J. C. Minor. We trust it will raise the ethical as well as scientific tone of the resort where it is published. Cremation has an organ in a new journal called *The Urn*, published in this city. We are told that cremation has come to stay, and that drift must yield to push. Sanitation seems to be more popular than medicine in Texas. A new journal called the *Texas Sanitarian* has just appeared. It is published at Austin, and edited by Dr. T. J. Bennett.

Sir Morell Mackenzie was one of the best known and most hated of all the physicians in English society, and although the best known and most hated, he was by a very large circle the best liked of any of the members of his profession. He was a kind-hearted, genial, courageous man, who built up a great practice and was correspondingly disliked by those whom he had distanced in the race. The professional accusation against him was that he was too much of an advertiser—not in the vulgar method of advertising, but by the more astute arts which are familiar to those who are past-masters in the art of pushing themselves. Such, at least, was the kind of scandal that used to be talked by those who hated the successful throat doctor who knew everybody, attended to everything, and succeeded in creating for himself such a position that, when the Emperor Frederick was smitten with his fatal disease, it was to the hands of Sir Morell Mackenzie that the illustrious patient was delivered, with such results as the whole world knows.—*Review of Reviews.*

Darwinism so far a Failure.—Darwinism has a strong foe in Professor Virchow. The following is an extract from his address on the subject delivered before the Anthropological Congress in Vienna: "Since the Darwinian theory of the origin of man made its first victorious mark, twenty years ago, we have sought for the intermediate stages which were supposed to connect man with the apes; the proto man, the *pro anthropos*, is not yet discovered. For anthropological science the *pro anthropos* is even a subject of discussion. At that time in Innspruck the prospect was, apparently, that the course of descent from ape to man would be reconstructed all at once; but now we cannot even prove the descent of the separate races from one another. At this moment we are able to say that among the peoples of antiquity no single one was any nearer to the apes than we are. At this moment I can affirm that there is not upon earth any absolutely unknown race of men. The least known of all are the peoples of the central mountainous district of the Malay Peninsula, but otherwise we know the people of Terra del Fuego quite as well as the Esquimaux, Bashkirs, Polynesians, and Lapps. Nay, we know more of many of these races than we do of certain European tribes; I need only mention the Albanians. Every living race is still human; no single one has yet been found that we can designate as simian or quasi-simian. Even when in certain ones phenomena appear which are characteristic of the apes—*e.g.*, the peculiar ape-like projections of the skull in certain races—still we cannot say that these men are ape-like."

Death of Dr. Lewis Johnston.—The following resolutions were adopted at a meeting of the Cape Breton Medical Society held in February:

Whereas, By the sudden death of Dr. Lewis Johnston, a breach has been created in the membership of this Society and in the ranks of the medical profession of Cape Breton;

Resolved, That we, the members of the Cape Breton Medical Society, in regular session assembled, do now express our great regret at the loss of our professional brother; and that we place on record our profound sense of his great worth as a friend and as a citizen; but more especially as a physician, and as a member and co-worker with us in this Society;

Resolved, further, That our deepest sympathy be extended to the family thus so unexpectedly deprived of its widely respected and distinguished head.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 18, 1892.

Alfred L. Loomis, M.D., President, in the Chair.

Mutilations of the Library. — The Committee on Library reported two mutilations of books, the first to occur in a number of years. It was supposed that persons not members of the Academy must have committed the deed. Members were requested to report any act of the kind which might happen to come under their observation while using the library.

Superior Maxillary Neoplasm Removed by Rouge's Operation; Recurrence.—Dr. W. F. Chappell presented the patient, a girl, aged two years and a half. At the age of eight months she fell from her mother's arms to the floor, striking the face. No bruise or abrasion was to be seen, but the child complained of the right side of the nose hurting her. Two weeks later the mother noticed a small swelling over the site of the injury. The lower lid was a little puffed. This increased and the child had hemorrhages from the nostril at intervals during a month. When she came to Dr. Chappell's department of the Manhattan Eye and Ear Hospital the swelling at the right side of the nose was of the size of a hickory-nut, was circumscribed, hard, and pointed. It was seemingly continuous with the nasal bones, but proved to be on the superior maxillary when removed by Rouge's operation. It was a hard, bony mass, of cancerous nature. For a month there was no recurrence, but now it had again attained a very considerable size, encroaching on the orbit and the alveolar process, and markedly disfiguring the face. Abscesses had been opened at the lower lid of the right eye. He asked for advice as to treatment.

A New Snare.—Dr. Morris J. Asch exhibited a snare which he had recently perfected. It could be operated by one hand, the loop could be enlarged or diminished while in position, the wire readily disengaged, and a fresh hold taken. The hand and finger motion in using it was like pulling on the trigger in shooting off a pistol.

Case of So-called Laryngeal Vertigo or Laryngeal Epilepsy.—Dr. Wendell C. Phillips reported the case. He said that of the various neuroses of the larynx none were so rare or unique in characteristics as that described as laryngeal vertigo, laryngeal epilepsy, or complete glottic spasm in adults. So few cases of this affection had been reported that it would seem the duty of observers to report such as might come under their care. Lennox Browne was first to mention the disease in any work on diseases of the throat, but it was first described in 1876 by Charcot. Since that time about twenty-five cases in all had been reported.

Dr. Phillips's case occurred in a robust-appearing Englishman, aged fifty; no neurotic family history. His friends called him excitable. For ten years he had been under severe mental strain from business worry. A year ago he had his only attack of articular rheumatism. Never had venereal disease, muscular rheumatism, gout, never used tobacco or snuff, took ale or beer at meals in moderation. July, 1891, he stepped into an open trap, struck on the hip, was badly stunned, but did not lose consciousness. Was in bed eight days, but referred all his symptoms to the hip; no disturbance referable to the head or spine, but was very nervous. Aside from this, had never had any fright, shock, convulsions, or fits. Had never had vertigo in any form, but had had what he called bronchial catarrh for several winters. His attacks of coughing were always accompanied by a profuse discharge of frothy mucus. Physical examination revealed very little except coarse râles. The heart was slightly hypertrophied, and its action weak.

The patient first came under Dr. Phillips's notice December 20, 1891. Three weeks previously he had taken a cold, which had followed about the course of colds of previous years until a week before, when the cough became more violent and paroxysmal. Two days before, during a paroxysm of coughing, he had suddenly, without premonition, fallen to the floor upon his back, entirely losing consciousness. The attack lasted but a few seconds, when he arose, feeling perfectly well, with no pain, no unpleasant feeling. There was no vertigo before or following the attack. The sensation must have been exceedingly pleasurable, for he said: "I felt as though I had been in heaven."

Following this he had an attack nearly every day, some occurring while he was in bed. If standing he invariably fell upon the back, and the attack always came on during a paroxysm of coughing, although not all paroxysms of coughing caused an attack. He did not bite his tongue, foam at the mouth, groan, or shriek; but on several occasions his mouth twitched convulsively during the attack and his eyes remained open. He had in all twenty fits, and one day had five between 3 P.M. and 9 P.M. His wife said he turned blue, and loss of consciousness would last five to fifteen seconds. On two occasions he complained of a sensation of pressure in the arms, and again of "smarting of the brain."

Examination of the air-passages revealed a generally hyperæmic condition, with no specially sensitive areas. There was polypoid degeneration of the middle turbinated bones, and an exostosis of the septum. The uvula had been amputated thirteen years ago. There were no signs of paralysis of the vocal cords.

After about ten days' treatment the attacks entirely disappeared. The treatment has been dietetic, a cathartic, bromide of sodium, and five minim capsules of eucalyptol four times a day. The eucalyptol relieved the cough and profuse discharge in a few days, and to this he attributed the recovery.

Regarding the name to be given the affection, Gray held views opposed to those of Charcot, claimed that it was totally unlike the vertigo of Menière, and called it laryngeal epilepsy. McBride, Russell, Knight, Gleitsmann, and others thought it was due to disturbance of the cerebral circulation. The author thought that absence of vertigo in so many cases would preclude its use as a name for the condition, while the term epilepsy more nearly met the requirements. He suggested the term laryngeal syncope. The pleasurable sensation might be attributed to asphyxia.

The author concluded with remarks on the treatment, and spoke highly of eucalyptol in nasal, laryngeal, and bronchial affections with free discharge. It was superior to the oil of eucalyptus.

Dr. D. B. Delavan favored the term laryngeal crisis. He had seen two cases, one in the care of Dr. Starr, the other of Dr. F. Tilden Brown. In both there was marked laryngeal congestion and irritation. The attacks came on during violent cough, and were attended by loss of consciousness. Being consulted, he amputated the uvula, treated the pharynx a short time, when recovery took place.

Dr. E. D. Fisher said a similar condition was met with in locomotor ataxia, but not oftener than other neuralgic crises. In looking over the history of cases he had found little which would enable one to determine the nature of the affection or seat of its lesion. He was inclined to think it was of cerebral origin, perhaps some affection of the laryngeal cortical centres at the base of the third frontal convolution. It differed from epilepsy in that the latter was very intractable, while most cases like the one reported by Dr. Phillips recovered.

Dr. Armstrong said he presented a case of this kind before the Academy in 1879, and took the position that it was due to irritation of the pneumogastric nerve, and not to a cerebral lesion or fulness of the cerebral vessels caused by interrupted respiration.

Another Case.—Dr. James E. Newcomb related a case which he had recently seen but had not yet published. It occurred in a German, a dispensary patient. The attacks were similar to those described by Dr. Phillips, except that there was not complete loss of consciousness. If of epileptic nature, it would be classed as *petit mal*, while Dr. Phillips's would fall under the head *grand mal*. Examination of the throat would bring on prolonged paroxysms of coughing, and a discharge of tenacious mucus from the mouth but not through the nose. There was intense congestion of the throat and enlargement of the tonsils. Local treatment greatly relieved the frequency and severity of the attacks, and he inferred from the fact that the patient ceased his visits and could not be found again that he had entirely recovered.

Case of Stenosis of the Larynx Following Fracture Treated by Intubation.—Dr. C. W. Stimson related the case and exhibited the patient, a man, aged thirty-nine, first seen by him January 24, 1890, when he gave a history that three weeks previously he had fallen a distance of eight feet, striking the throat on a projecting screw. After extracting the screw he suffered from increasing laryngeal dyspnœa, and had extensive emphysema of the upper part of the neck. Suffocation being imminent, a physician performed laryngotomy. Dr. Stimson described the appearance of the larynx as nearly as it could be made out by laryngoscopy in its swollen and distorted condition. The lumen of the larynx was much narrowed, the right side was more encroached upon than the left; there was very little motion; a pendant was seen which looked like the remnants of a vocal cord torn by the screw. While the breathing was interfered with, it was not until some time that laryngeal dyspnœa became so marked that it was deemed necessary to resort to intubation and thus exert continuous pressure against the projecting and narrowing surfaces. The main cause of the stenosis seemed to be the distorted sides of the thyroid. The man's larynx was low, and at the first attempt he was able to introduce only the smaller of the hard-rubber O'Dwyer tubes, but when this was coughed up the following day he without difficulty introduced the tube of middle size. At present the patient was wearing a still larger tube. There had been no return of the dyspnœa. There was still some laryngeal deformity, but less swelling, less hypertrophy, much larger breathing space. The author made some remarks upon the intubation in these cases, and said that it was best to introduce the tube by the aid of the laryngeal mirror, especially if the larynx were low down. Different patients differed greatly in tolerance of the tube.

Discussion on Hypertrophy of the Tonsils. — Dr. Morris J. Asch was requested by Dr. Knight, Chairman of the Section on Rhinology and Laryngology, under whose auspices the meeting was held, to open the discussion on this subject. He treated of it under the heading, "When to Operate and the Method." The character of the trouble was often manifest in the child's physiognomy. The mouth half open, the nostrils dilated, evidence of embarrassed respiration, appearance of stupidity —such were symptoms often observed in marked tonsillar hypertrophy. He believed authorities were agreed that interference with the respiration could bring about arrest of mental as well as of physical development. One principal symptom which had led him to operate was snoring at night. Further, there might be otitis, due to the enlargement of the tonsils; and there was a tendency in these patients to quinsy, due, he thought, to their breathing through the mouth instead of through the nostrils. The patient might also complain of deglutition.

Regarding surgical methods, they consisted to-day chiefly of two, namely, removal by the knife or by the cautery. It was generally supposed that the method by the cautery was new, but this was not true; it was as old as medicine, but it had largely dropped out of use until recent years, and not until still more recently had it been applied with the skill made possible by improved methods. Two forms of actual cautery were mostly in use, namely, electro-puncture and electro-excision. Electro-puncture, the speaker said, could not become popular among general practitioners, owing to the number of applications and time which it required. The galvano-cautery loop was sometimes made use of for excising the tonsil. The cold snare had also been recommended for the same purpose, but he doubted whether it would come into favor since it produced extreme pain.

Regarding excision of the tonsil by the knife or guillotine, he said it was done frequently, yet it was an extremely dangerous operation. He did not mean to say that it was a difficult operation, but there might be abnormal arterial distribution causing hemorrhage which could not be controlled. Danger of serious hemorrhage could be referred to three sources: 1, abnormal distribution of vessels; 2, venus plexus behind; 3, profuse capillary bleeding. The vessels being sclerosed in hypertrophy of the tonsil, they were liable to remain open when divided and thus cause serious hemorrhage. There was no other way to control hemorrhage, he believed, than by pressure. In a case where a loop of the carotid artery entered the tonsil and was divided during excision, the patient died in a few seconds. He gave preference to Mackenzie's modification of the tonsillotome in the way of cutting instruments. He would not operate simply because a tonsil was very large; but would operate if it interfered with respiration, or caused frequent attacks of quinsy, or interfered with audition.

The Existence of a Tonsil Should be Regarded as a Disease.—Dr. F. H. Bosworth said that ten or eleven years ago he had made the assertion that practically there is no tonsil in the healthy throat. The existence of a tonsil should be regarded as a disease to be dealt with summarily and promptly. As to symptoms, he did not think snoring and interference with breathing was to be attributed to enlarged tonsils, but rather to enlarged so-called third tonsil or enlarged glands in the pharynx. He did not believe that enlarged faucial tonsils gave rise to difficult breathing, or nasal catarrh, or difficult hearing.

What tonsils should be cut out? All tonsils should be cut out. Tonsils meant diseased lymphatic tissue, which if it remained a sufficient length of time would then continue to exist during life. It had been said that tonsils disappeared at puberty, but he could say they did nothing of the sort. They shrank up at puberty, but in doing so they became a source of no inconsiderable trouble, especially in forming places for the accumulation of mucus which would undergo cheesy degeneration. Continuing, Dr. Bosworth asked, What constitutes a healthy tonsil? How were we to tell? How many children were in a state of absolute health regarding their lymphatic glands? When the glands were enlarged he assumed that they were diseased. Yet he would not say remove every tonsil. But as soon as a so-called enlarged tonsil caused symptoms he would remove it.

As to mode of operating, he condemned the electro-puncture, which sometimes required even fifty or sixty sittings, whereas a second was sufficient time by the knife. Moreover, the reaction following electro-puncture stimulated the formation of connective tissue, and created a worse condition than the one which it was intended to remove. As to the knife proper, it required a wonderfully skilled surgeon to use it safely in a struggling child. He preferred the French tonsillitome to Mackenzie's. He did not consider tonsillotomy a dangerous operation; he knew of no recorded death from it by a surgeon. No surgeon would cut the carotid artery. He had seen no serious hemorrhage in the child, but in adults there was more or less perplexing bleeding, and he there employed the cold snare. As to removal of part of the tonsil only, he regarded it about as justifiable as taking off only a part of a uterine fibroid. Something was left which could be of no further use than to act as a trap for disease.

Tonsillotomy not Dangerous.—Dr. D. B. Delavan thought there was a great deal more truth than fancy in

Dr. Bosworth's views of the pathology of the tonsils. He thought the tonsil should be treated surgically when it was hypertrophied to the extent of forming an obstruction in the naso-pharynx, or when it caused recurring attacks of follicular tonsillitis. As to hemorrhage, he had seen only one instance of marked hemorrhage in a child, and that patient happened to be of the hemorrhagic diathesis. The tonsillitome was best in children. He would employ the cautery only where the knife was specially contra-indicated or the patient would not allow it to be used. Keep the first clot on if possible, and there would be quick healing. He thought that ere long men would cease to burn the throat and nose as much as at present. He would not advise the general practitioner without special instruction in throat difficulties to do tonsillotomy.

Congestion versus Hypertrophy.—Dr. O. B. Douglas had been in the habit of regarding the enlarged tonsil not as necessarily hypertrophied; it might be simply inflamed or congested. Instead, therefore, of always removing it, he now first tried to reduce its size by astringents, etc., or, if there were a cause outside, he treated that. In the case, however, of enlarged or pharyngeal tonsil, he would remove it. A common source of enlargement of the tonsils was a diseased condition within the nose, which should be treated. Often there was connection between the enlarged faucial tonsil and anterior pillar of the fauces, and by separating them the tonsil would frequently be caused to subside. Where there was interference with breathing, deglutition, etc., remove the tonsil, but not otherwise. He believed it was often removed where it should not be.

Is the Specialist Extreme?—Dr. Beverley Robinson remarked that if one looked upon the tonsils from the specialist's point of view, it would seem that all would have to come out. He was decidedly of the opinion that not every tonsil meant disease, or that every enlarged tonsil should come out. Nor did he believe that in the majority of cases where the tonsil called for surgical treatment that the whole gland should be removed. Further, he believed that the danger from hemorrhage was much increased by removing the entire tonsil. Again, he believed that disease was more likely to follow complete excision than partial excision. He felt some anxiety in taking out large tonsils in children, for there undoubtedly were cases of death due directly or indirectly to the operation. If one wished to resort to galvano-puncture, he was convinced that it would seldom be necessary to hold more than half a dozen sittings. The cautery was specially useful in breaking up crypts in which mucus lodged. Here it was more rational than total or partial excision.

Dr. Robinson said he knew one specialist in the city who removed a great many tonsils, but did not have his own, which were enlarged, operated upon. He seemed to think there were a good many people who were more willing to act out their ideas on others than to be experimented upon themselves.

Indications for Galvano-Puncture. — Dr. Knight, chairman of the section, being called upon, explained the position which he held with regard to galvano-puncture, with which his name had become somewhat connected. There were only four conditions in which he would resort to galvano-puncture instead of excision: 1. Where one could distinctly recognize vascular anomaly. 2. Where the tonsil was deeply buried, flat, diffuse, perhaps adherent with the pillars, and could not be included readily in tonsillitome. 3. In hæmophilia. 4. Where the patient absolutely refused to be cut. Regarding the number of sittings, he called for fewer than formerly if the patient were tolerant of a number of punctures at a sitting. The electric wire loop was useful if the patient was willing to put up with the greater suffering.

Enlarged Tonsils and Stupidity.—Dr. A. Jacobi thought there was less difference of opinion between the speakers than there seemed to be. The stupidity, which had been explained by interference with the respiration, he would attribute to the connection between the glands in the pharynx and those within the cranium, the latter being diseased secondarily, directly influencing cerebral or mental function and development. As to abscesses being caused by electro-puncture, this should not be if the method were practised aright; that is, do not leave blind pouches by the puncture. Several attacks of follicular abscess constituted a good indication for surgical treatment of the tonsils.

Opposed to Wholesale Tonsillotomy.—Dr. Agramonte opposed wholesale tonsillotomy, if for no other reason than the fact that some deaths had undoubtedly been due to the operation. Yet where the enlarged tonsils obstructed breathing, gave rise to attacks of tonsillitis, or diphtheria, etc., they should be removed. One should always be prepared to meet hemorrhage; have the cautery and other agents convenient. Before operating, feel for pulsation in the tonsil with the finger. He had seen frequent attacks of follicular tonsillitis and diphtheria cease in the adult after tonsillotomy.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DISCUSSION AT THE PATHOLOGICAL SOCIETY ON PHAGOCYTOSIS AND IMMUNITY—SPEECHES BY DR. SIMS WOODHEAD, PROFESSOR KLEIN, AND MR. KANTHACK.

London, February 20, 1892.

An important debate on "phagocytosis and immunity" is now in progress at the Pathological Society of London. It was opened at the last meeting and is to be continued at the next. The president (Sir George Murray Humphry, of Cambridge) defined the limits of the discussion by stating that its object was to show how the blood dealt with morbid material introduced into it from without.

Dr. Sims Woodhead then opened the discussion in a lengthy and elaborate address in which he reviewed the work on the subject which had been done by various workers up to the present date. It was impossible, he said, to discuss the relation of phagocytosis to immunity without introducing much concerning chemotaxis, and what had been aptly spoken of as the humoral theory of immunity. The former of these was not antagonistic to, but might be actually looked upon as an essential part of, phagocytosis. The latter, however, was held to be in direct opposition to Metschnikoff's theory, though an attempt was now being made to combine the two—an attempt which was gaining ground, though it was founded on little experimental basis.

Taking first the question of phagocytosis from its physiological standpoint, it had long been recognized, he said, that inert particles finding their way into the animal system, or even introduced into the blood of a newt directly after it had been drawn, were rapidly taken up by leucocytes, and, in the body, from them, by the connective or other fixed tissue-cells. A similar process had been observed by every pathologist who had examined a healing wound, a section of the lung, or the cells of a normal spleen. The significance of the process was first pointed out by Haeckel who, comparing the leucocyte of the newt with those of the lower amœboid organisms, indicated that this must be the remaining evidence of a normal process of nutrition common to amœboid cells in whatever position they existed. Attention was first drawn to the part played by phagocytic cells in the production of immunity by Carl Roser, who, in 1881, described examples of the possession of this phagocytic power by the cells of both plants and animals, and of its importance in the resistance by them to the attack of pathogenic fungi by which they were sometimes invaded. He maintained

that the mobile amœboid cells of the animal body had the power of taking in and digesting even living micro-organisms which in non-resistant or non-immune animals had the power of withstanding the attacks of the devouring cells. As the result of his observations, he was convinced that this power of taking up micro organisms must be an essential factor in the immunity enjoyed by non-susceptible animals. At this point Metschnikoff took up the question. He confirmed Haeckel's observations, and further demonstrated the fact that certain amœbæ and flagellated or ciliated organisms in the normal condition depended for much of their nourishment upon bacteria and fungi, which they destroyed in large numbers, taking them into the substance of their protoplasm, extracting from them all nutritive substance, and then throwing out such matter as they could not utilize. Dr. Woodhead then discussed at some length the subject of physiological phagocytosis and the question of the source of macrophages and microphages. He remarked that the power which amœboid cells in the higher animal organisms possessed, viz, the power of removing innocuous material, was perfectly different from the phagocytic function exerted by the single-celled amœbæ or by the mesoderm cell of the lower invertebrates, which actually attacked living organisms and depended upon this power in a very large degree for their nourishment. In the process of development this attacking power was to a certain extent lost, though the scavenging power might still remain. But although in great measure lost through disuse, this attacking power remained as one of the potential faculties of the primitive protoplasm, and—under suitable conditions—might again be brought into play. The scavenging leucocytes might regain their original attacking function to such an extent that they might not only remove dead tissue and innocuous micro-organisms, but actually attack, ingest, and destroy micro-organisms to which, under ordinary circumstances, they would exhibit the greatest aversion, or to which they would succumb if brought into contact with them. This was the key to Metschnikoff's whole position. This special stimulation of the leucocytes must be commenced gently and gradually increased, so that we might say there was a gradual preparation or acclimatization of leucocytes before they could contend successfully with pathogenic micro-organisms, and before they could regain their phagocytic functions from the nutritive point of view—a function that might become so marked that the secondary or scavenging function was relegated to a comparatively unimportant condition.

Dr. Woodhead then passed on to the consideration of tissue resistance and tissue cells. He said Metschnikoff drew a marked distinction between leucocytes and cells derived from connective tissue—a distinction, however, which did not seem to hold good in all cases. He then discussed the action of phagocytes on bacilli, and described the method by which Metschnikoff had (in the case of anthrax) shown that the bacilli were not killed before being taken into the substance of the cell, but still retained their power of vegetable reproduction. The following subjects were then passed in review at some length: chemotaxis (positive and negative), antibiotic substances, the behavior to toxines of the leucocytes of immune animals, and the question of the production of immunity by varying processes.

In concluding his address, Dr. Woodhead said that in all our researches on immunity we were confronted with the question, "How is it that immunity is conferred for one disease only, or certainly for one series only?" Why should an attack of vaccinia or variola be necessary to ensure protection against another attack of variola? The exhaustion or assimilation theory was early found insufficient to account for it, as it also was to explain the different action of the bacillus prodigiosus, which, while lessening the action of a dose of anthrax, increased the virulence of Chauveau's bacillus, or charbon symptomatique. The local immunity theory was also found inadequate, and local immunity as a factor in immunity had had its day. The adaptation theory, or cellular chemical theory advocated by Klebs and Grawitz, Ribbert's theory of massing of leucocytes, and Metschnikoff's phagocyte theory had in turn ousted the retention theory advocated by Wernich and Chauveau, while the serum bactericidal theory had come forward to rout this if possible. With regard to the latter, even should the bactericidal power of serum be proved to exist, it must depend directly upon changes produced in the cells—changes which must be equally specific if what we thought we knew about immunity was at all to be trusted. Immunity was specific, while this bactericidal power of serum was very general in its action unless we accepted the view that the blood must be loaded with a fresh bacteria-killing material for every disease we contracted from childhood upward.

Professor Burdon-Sanderson then spoke and declared himself hostile to the theory of phagocytosis. He said all physiologists admitted the specific power of the organism to protect itself, and that in many instances the intervention of leucocytes was associated with this power. Many pathologists, however, declined to vest protective power in the leucocytes or to recognize any direct relation between their activity and the specific exciting causes of specific diseases; they preferred to attribute the phenomena of phagocytosis to the ordinary endowments which leucocytes manifested, not merely in disease but under normal physiological conditions; such, for example, as those under which they acted in the processes by which effete structures were absorbed.

Professor Klein followed, and expressed his inability to accept arguments for the phagocyte theory. He said the question embraced a wider field of observation than was included in the views already advanced. Some investigators included all instances in which bacteria were found engulfed in cells. This was the first error, and he illustrated his remark by exhibiting a number of microphotographs showing a dozen instances of micro-organisms contained in cells which were breaking down under their influence, thus reversing the process. The influence of chemotaxis, as shown in the cells of the bile ducts in which psorosperms were growing, was of quite a different nature to that asserted. After criticising some observations of Emmerich, Mattei, and Metschnikoff, he asked if there were any well established cases in which bacilli were known to have been destroyed by lymph or other juices. Dr. F. Andrewes, he said, was carrying out some experiments which showed that pus, already dead, and even when twenty-four hours out of the body, had a rapidly noxious effect upon these organisms. When anthrax was introduced into the dorsal lymph sac of a frog, it was hours before any bacilli were seen enclosed in cells, the lymph itself being capable of destroying them. Dr. Klein then described some experiments in which it had been found that a rapid diminution in bacilli occurred within two hours of their introduction into the body. This was not at all in accord with the time observed in their gradual approach and engulfment by cells, and he thought it was much simpler to assume that the juices of the body were germicidal, though Buchner's explanation, he admitted, gave little account of what took place with regard to the bacilli after they had been weakened by exposure to the juices.

Mr. Kanthack said he assumed that at the present date no doubt existed as to the occurrence of phagocytosis, but the question was whether immunity from infective diseases or lesions was caused by phagocytosis, *i.e.*, through the phagocytes alone and nothing else. He discussed in succession the following points: 1. The influence of the body fluids. 2. Chemotaxis. 3. Phagocytosis. As to the first of these, he concluded that at the present state of our knowledge it was impossible to assert that the living plasma was of no consequence, and he related numerous experiments showing the action of the body fluids; he would not, he said, claim more for the body fluids at present. Chemotaxis had of late been in-

troduced as a welcome support to the theory of phagocytosis, but I do not gather from what Mr. Kanthack said that he considered that it taught us much as to the acquisition of immunity. As to phagocytosis itself, he fully acknowledged that it existed and that it was an important phenomenon during and after the acquisition of immunity, but the exclusive phagocyte theory was both inadequate and unsatisfactory. He enumerated a few of the difficulties which had occurred to him. 1. By causing fever artificially in an animal the army of phagocytes—both of the so-called lymphocytes and of the larger elements—was increased tenfold, but on inoculating the animal with anthrax it would die as usual. 2. This showed that the increased number of phagocytes was not in itself sufficient, but that they required special training, and this was the most unsatisfactory part of the theory. 3. The occurrence and importance of vaccine fever during the process of immunization pointed to more general changes than a mere change of habit of the phagocyte alone. 4. Emmerich had shown that changes existed in all the tissues, for he was able to protect animals by inoculating them with the tissue-juices of immunized animals. 5. Some of the methods of immunization pointed strongly to general changes in the body. 6. Phagocytosis did not explain many of the phenomena he had described. Mr. Kanthack therefore maintained that we could not hold any one process primarily responsible for the artificial production of immunity. The primary cause of immunity must be sought beyond the leucocyte or phagocyte, and also beyond the fluids of the body, and, according to the maxims of cellular pathology, depended on changes in the cell-life of the organism, which at present we were unable to understand. It was in consequence of these as yet obscure molecular changes that phagocytosis and the other phenomena observed after or during immunization appeared, but none of these alone could be considered the cause of immunity.

OUR BERLIN LETTER.

(From our Special Correspondent).

THE INFLUENZA BACILLUS AND THE EPIDEMIC OF INFLUENZA—WHAT IS YET TO BE LEARNED CONCERNING PREVENTIVE MEASURES REGARDING THE SPREAD OF THE EPIDEMIC—ANOTHER ALLEGED CURE FOR CANCER—CRYSTALLIZED AGAINST LIQUID CHLOROFORM—LOCAL ANÆSTHESIA IN A NEW PHASE.

BERLIN, February 10, 1892.

MEDICAL interest is still centred in the influenza, owing to the large mortality of those affected, and also to the uncommon number of complications associated with the disease. A very elaborate work on influenza will soon be published under the auspices of the Society for Internal Medicine, and will contain contributions from numerous celebrated authorities who have been assisted in their work by observers from all parts of the globe. It is then to be hoped, from a statistical, clinical, and historical point of view, many of the vexed questions concerning this mysterious disease will be settled. The fact that the epidemic is on the wane will be hailed with delight by all people, excepting, perhaps, the discoverers of the influenza bacillus, Messrs. Pfeiffer and Canon, and many others, scientifically speaking, regret the comparatively restricted sphere of their observation.

The most important questions as to how long the influenza bacillus can live, how the disease is transmitted from man to man, and how an inoculation of the pure culture of bacilli can generate the disease and render the system thereby less liable to the complications, are still practically unanswered Nobody to-day questions the coexistence of the bacillus and the disease, and in this give due credit to the investigations of Pfeiffer and Canon. The priority of the discovery is credited in France to Babes, who published in 1890, in the *Centralblatt für Bakteriologie*, an account of the bacilli and micrococci found in influenza, without emphatically saying, however, that this or that microbe caused the disease. The French dispute the priority of the German discovery. Babes has just written a paper wherein he gives credit to the discoverers of the bacillus (Pfeiffer and Canon), but adds that it is too soon to expect great practical and therapeutical results therefrom. The most important point in the *rôle* of the infectious diseases will be to discover their prophylactic influences. It will be necessary, as in diphtheria, abdominal typhus, and tuberculosis, to carefully examine the excreta of influenza, and in this we may note some relation of cause and effect. That new specifics for the treatment of influenza should turn up daily is no wonder, as each would-be discoverer naturally desires to become famous as a benefactor in this line. But so much misrepresentation has been done in the therapeutics of the last ten years that every new remedy is looked upon with deserved suspicion.

The same fate as to general recognition of the specific treatments in influenza awaits that of Professor Adamkiewicz in Vienna, who has a new remedy for cancer. Recently in the Medical Society of Vienna he presented a case of cancer as cured. Professor Billroth and Professor Kumbrat, who were present, were not convinced of the diagnosis or cure. Here in Berlin, where Adamkiewicz is well known, owing to his therapeutic researches, his announcement is regarded sceptically, more so because he has (which by the way is fashionable) not yet given his remedy nor his method a trial. Such announcements would be received in a very quiet way, but in each case the laity in some way hears of it, and takes a very active part in it, and believes that all opposition is caused by jealousy, and consequently seeks to rush all cancer patients to the new prophet and neglect the operative treatment which might ultimately save them. We shall, however, soon hear every detail concerning the method, as he has announced a paper on the subject, to be read at Leipsic, in the beginning of April, at the Congress of Internal Medicine.

At almost the same time we shall have here in Berlin a meeting of the Congress of German Surgeons, but I hear this will be postponed possibly until May, in order that the memory of Langenbeck can be honored by the dedication of the Langenbeck House.

It had been the lifelong wish of Langenbeck that the German surgeons should have a home of their own, and now it is about to be consummated, thanks to the munificence of the late Kaiserin Augusta and Kaiser Frederick III., as also to the present Kaiser, the numerous home and foreign societies, and our American friends who have contributed 1,000 marks.

The site is next to the Surgical Clinic, wherein Langenbeck worked faithfully many years. Along with this building Berlin will have a proper meeting place, with an auditorium which will comfortably seat several hundred people; a second hall will seat about one hundred people for smaller meetings. There will also be rooms for microscopical and laryngoscopical work; there will be additional rooms suitable for special demonstrations.

There will be arrangements to darken the meeting-rooms so that microscopical specimens can be enlarged on the screen, and thus clearly demonstrated. Besides, above these will be ample room devoted to the library of the Berlin Medical Society, and a large room for the maintenance of all surgical and other specimens. It is needless to add that all modern comforts, as electricity, hot air, and steam, will be utilized.

The scientific programme of the coming Surgical Congress, Honorable President Professor v. Bardeleben, has not yet been announced, at the same time it is understood that the chloroform question will again be under discussion. It has assumed a different attitude since Professor Raoul Piczet, who has lately moved to Berlin from Geneva, has been able by applying very low temperatures to produce a crystallized chloroform, which he claims can by a certain process of recrystallization be made absolutely free from impurities.

It has been hoped that all disagreeable symptoms, such as chloroform intoxication and vomiting, and other unpleasant effects on the nervous system, could be prevented thereby, but more especially, the ever-recurring deaths by narcosis.

The application has as yet been restricted to a limited number of patients, still it must be said that Piczet's chloroform is not altogether free from danger, for in one of our large hospitals where it was used in a case of laparotomy, diastole of the recti muscles was noticed after the operation.

From other sources we hear great praise given to the new preparation, which is considered superior to the best fluid chloroform.

This striving to obtain a pure chloroform is somewhat antagonized by a desire on the part of others to perpetually banish chloroform from surgery, and to substitute local anæsthesia for it. The idea is not new, but the method of its application is arousing considerable attention.

One of our young surgeons, Dr. C. Schlerch, in Berlin, has used for some time a combination of ether-cocaine—the ether is applied externally in the form of spray and the cocaine ($\frac{1}{4}$ to $\frac{1}{2}$ per cent. solution) hypodermically by very deep injections into the whole area of the operation. Instead of cocaine some are using bromide of potassium, some morphine, but not as successfully as the former. Before each incision cocaine is injected until pain is not felt by the patient. With the aid of this method, this surgeon has not only succeeded in operating upon hæmorrhoids, phlegmonous abscesses, and doing plastic operations, but also the most complicated operations, such as laparotomy, tracheotomy, nephrectomy, and even gastrostomy.

Dr. Boas attended one of these gastrostomies, and informed me that the patient lay quietly on the table during the whole of the operation and chatted with the assistants, and although the operation lasted half an hour showed no sign of discomfort. But not all cases show as brilliant result as have just been described, for in some it was necessary to use chloroform as the only means of relieving pain. Still, we are forced to admit that in the above-described local anæsthetic chloroform will have a hard opponent, inasmuch as the public at large believes in anything that relieves pain without producing complete insensibility. It is also most admirably adapted for the country doctor, who, not always having suitable assistants with him, can undertake any and all operations, and, no matter how long they take, need not fear the effect on the heart. On the whole, there is no danger in local anæsthesia, and we can be assured that chloroform will henceforth rarely if ever be used in minor surgery, and it may not be very long before the method will be much improved and used exclusively.

THE HEALTH RESORTS ON THE RIVIERA.

II.—NICE.

(From our Special Commissioner.)

RECENT ARRAIGNMENT OF NICE—THE AUTHORITIES ON THE ALERT—PURITY OF THE DRINKING-WATER—THE BOARD OF HEALTH—PHYSICIANS AT NICE—STATISTICS OF MORTALITY—PRESENT SYSTEM OF DRAINAGE—NEW PLANS FOR SEWAGE DISPOSAL—CLIMATE AND PREVAILING DISEASES—NO TYPHUS FEVER AT NICE—MEDICAL INSTITUTIONS.

NICE, February 10, 1892.

NICE is the gay capital of the most picturesque littoral in all the world. Partial Nature has showered some of her choicest gifts into the willing lap of this lovely town in sunny Provence. Its distant mountain ranges, the winding vallons of its nearer hills, the Carnaval and Batailles des Fleurs, its palm-fringed Promenade des Anglais, the stir and bustle of its city life, the contrasting quietude of suburban villas, the theatres, concerts, turf, regattas, tennis, and what not, combine to give familiar enjoyment to increasing crowds of winter visitors. It has been aptly called the Brighton of the Continent and the "Pearl of the Mediterranean."

In this modern development of gay life, at times a trifle over boisterous, the old-time claims of Nice as a health resort appear to have severely suffered. Yet the marvellous rise of the place received its first impetus from the early reputation of Nice as a winter station for invalids.

It cannot be denied, however, that its prestige in that direction has recently been rudely touched by certain alleged exposures. The climate of Nice was said to be very trying. Attention was called to its dirtiness, with the obligato accompaniment of noisome odors. The dangerous, dust-laden mistral, its lack of sanitary improvements, its moral turpitude, were all enlarged on. Its impending ruin was even darkly hinted at.

In face of this severe arraignment scores of people from all quarters of the globe continue to live at Nice. For the past eight weeks I have been making a personal study of sanitary and other matters here. I must own that I was favorably impressed by the hearty way in which the authorities assisted me in my labors. So far from wishing to conceal anything, the municipal officers made every effort to facilitate my investigations. The following note, sent by the Mayor to the President of the Board of Health, is one of many, and will illustrate the willingness of the authorities to co-operate with the RECORD Commissioner:—"M. le docteur E. C. Wendt, chargé par le *Medical Record*, de New York, de recueillir des renseignements sur les conditions sanitaires des villes du littoral, désirerait entrer en relation avec vous et connaitre les travaux du Bureau d'Hygiène. Je le recommande à votre bienveillant accueil dans l'intérêt de la ville de Nice. Tout à vous, le Comte ALZIARY DE MALAUSSENA, Maire de Nice."

As already stated, Nice has been disparaged on account of the alleged unwillingness of the authorities to effect necessary changes. But so far from pretending that the sanitation of their city is perfect, the Municipal Government is keenly alive to the necessity of certain radical alterations. The immediate improvement of their system of sewage disposal is in contemplation. I can state, on the authority of the Mayor, that a sufficient fund for beginning work is already available, and that by means of taxation enough and more could be raised to carry out the projected improvements. But before entering upon a description of the new plans, it will be well to briefly explain the present condition of things at Nice.

To begin with the drinking-water, I examined the sources whence it is taken, and found that they were mostly pure mountain springs. The Nice drinking-water is by many of the Niçois themselves, including physicians, confounded with the water conducted to the city in the open Canal de la Vésubie. The latter is, of course, quite impure, but it is supplied solely for street-washing, sewer-flushing, fire-extinguishing, and industrial purposes. The aqueduct of the Compagnie Générale des Eaux, built in 1867, is a well constructed, completely closed conduit. The trip to the main sources of St. Thècle is well worth making, if for the changeful beauty of the scenery alone. The way is along the old Turin state road. Passing the villages of La Trinité and Drap, you come at length to the mountain slopes, whence the water is taken. Beyond you plainly see that extraordinary human eyrie, the village of Peille, perched on a steep forbidding rock. There the Saracens once held unmolested sway, making piratical excursions into the surrounding lowlands.

The main spring of the Nice Water Company juts boldly out of a deep crevasse in a grotto of limestone rocks. It is at once collected into a clay pipe, which forms the beginning of miles and miles of aqueduct. A little lower down a second similar source is found, and a third one not far from this. The last named, the Comtesse source, is not free from suspicion, as the water wells up languidly through the clay soil, and contamination by

ground filtration from a few near-by houses is not sufficiently guarded against.

An additional irreproachable mountain spring is situated a mile away from these St. Thècle sources. It sends but a small volume of clear water to the aqueduct. The Nice water, as supplied by the company at small cost to the residents, is, therefore, a mixed water. It is hard, chalky, and very slightly acidulous to the taste. Those who can drink dilute lime-water may safely take it. Filtration is not necessary, but boiling would of course destroy the traces of organic admixture that it contains.

The bacteriological tests instituted by the health authorities, under supervision of Dr. Balestre, show that one source is not altogether what it should be, viz., the "Comtesse," at St. Thècle. As this gives but a very scant supply of water, it will probably soon be entirely suppressed. This would remove the only exception that can now be taken to the purity of the Nice drinking-water. The detailed results of bacteriological tests, though interesting, would occupy too much space here. The composition of the water is as follows :—

Analysis of the Nice Drinking-water, made by M. Durand-Claye, de l'École des Ponts et Chaussées.

Ingredients of one litre, evaporated to dryness.	St. Thècle.		
	Crevice in rock.	Source of Pré.	Peillon source.
	Gr.	Gr.	Gr.
Insoluble residue	0.010	0.004	Traces
Alumina and peroxide of iron	0.001	0.001	Traces
Chalk	0.000	0.085	0.050
Magnesia	0.016	0.009	0.040
Alkalies (various)	0.016	0.008	0.030
Chlorides	0.013	Traces	0.020
Sulphates	0.015	0.011	0.010
Organic matters	0.016	0.003	0.030
Carbonic acid and unclassified substances	0.054	0.059	0.060
Total residue of evaporation of one litre	0.212	0.180	0.240

There are also a number of wells in Nice. The water from this source is shown to be impure by bacteriological tests, and should be condemned.

The Board of Health has been established six years, and has in that period accomplished a great deal of good. It is hampered by the peculiarities of French law, for it cannot legally enforce its rules and regulations, although it can generally worry people into complying with its requests. Its functions are briefly these : to preserve a record of vital statistics, to inspect all foods sold in stores and markets, to test the purity of all wines before the latter can be sold, to inspect all schools, hotels, lodging-houses, and even private residences, and to report on all sanitary matters in connection therewith. The disadvantages under which the Board labors are these : There is no law making obligatory the notification of contagious diseases, no compulsory vaccination, no law compelling disinfection of suspicious premises, and no law which can force a physician to certify the cause of death in any of his patients. As a matter of fact, reputable physicians never refuse this information, but at the same time it is a serious drawback that the law cannot, at present, compel them to do so. Legislation on this point is, however, already under way.

It is one of the decided advantages of a large city that its pecuniary rewards attract good professional talent. Thus there is no dearth of competent physicians at Nice.

The death-rate of Nice will bear favorable comparison with that of any city in the world. And, what is more, it appears to be diminishing rather than increasing. In justice to the city, it should be borne in mind that, in calculating percentages, the permanent population is used as a basis. The census of 1891 gives Nice a population of 97,720. But as there is a large floating population, estimated to reach 30,000 or 40,000 during the season, and as many invalids go to Nice to die, it follows that the actual death-rate must be even lower than the official returns make it. Here are the figures, however, as given by the Board of Health :—

In 1883	30.75	deaths per 1,000.
" 1884	29 55	" "
" 1885	28.82	" "
" 1886	24.60	" "
" 1887	25.21	" "
" 1888	20.62	" "
" 1889	21.78	" "
" 1890	21.63	" "

The question of sewage disposal is the most important problem now before the authorities at Nice. The town has quite outgrown its present facilities for the proper discharge of waste matter. The trouble is not so much with the street sewers as with the totally inadequate and antiquated methods of house-drainage. The city has spent large sums of money in establishing a network of sewers that covers nearly all important points of the town. But landlords and lease-holders have been far less liberal than the Municipality. The house-pipes in many hotels and boarding houses, and even in some of the better class of villas, consist of old, insecurely-joined clay conduits. Properly ventilated traps and cut-offs are conspicuous by their absence from most places where they are imperatively called for.

The city has recently constructed eighty automatic sewer-flushing tanks, placed at the heads of all main drains. The capacity of each cistern is about two thousand five hundred gallons. When full, they suddenly discharge their contents by a simple automatic syphon arrangement. When the Vésubie water runs plentifully the tanks will fill and spout every few hours. At other times they discharge only four times in the twenty-four hours. Still, even this secures very fair cleansing of the sewers, as I have personally witnessed.

Two large iron pipes at present collect the sewage and carry it out to sea, one hundred yards distant from the shore. From a hygienic point of view not much can be said against this temporary make shift, as no odors arise from this source. Rowing about over the points where the sewage is discharged clearly proved the absence of bad smells, and showed that the well-known oxidizing properties of sea-water in motion are doing good work. At the same time it must not be forgotten that the Mediterranean is an all but tideless sea, and that æsthetic reasons alone would dictate the suppression of sewer pipes emptying near the beautiful Promenade des Anglais.

Several sewage contaminated water courses, coming down from the vallons of Nice, still exist. One, at the opening of the boulevard Gambetta on the Promenade des Anglais, is particularly offensive. Nevertheless, washwomen may be daily seen to clean (?) their linen in this foul stream. They seem to enjoy an immunity from sewer gas-engendered maladies, and they must surely be blessed with an enviable dulness of their sense of smell. No sewage is at present discharged into the Pallion River flowing through the town, all the old mouths of the sewers having been closed up.

The imperfections of house-drainage have already been mentioned. At the present time most hotels and private residences have cesspools, and, although the law forbids it, many of them are connected by untrapped overflows with the street sewers. This is, of course, a dangerous method, and will be entirely done away with as soon as the new system of drainage shall have been completed. Then there will be a *tout à l'égout* arrangement, which is, for large cities, the only safe and reliable method of sewage disposal. In Nice the establishment of such a system will, however, imperatively call for a complete overhauling of house-pipes, as well as the connection of house soil pipes with street sewers, under the supervision of expert sanitary engineers. Nothing short of this can be considered safe. And while the immediate expenditure may appear to be large, it will prove profitable in the long run.

Fully recognizing the shortcomings of their present system, the authorities are now considering two new plans for perfecting the same. The first of these is M. Bérard's plan. It is quite simple, and would be comparatively inexpensive. After rectifying, repairing, or newly-constructing a comprehensive system of street sewers, a large collecting conduit is to be built parallel with the shore line. This will carry the sewage down to the Magnan by a natural incline. Thence an iron conduit will convey it nearly five hundred feet out to sea. The advantages of this plan are that it is cheap, feasible, and measurably effective.

A more radical, but also vastly more expensive, plan is that of M. Masson, the Paris expert. It is, so far as known, merely an extension of the Bérard plan, with this difference: that in place of a natural incline, one or more pumps are to be used as a propelling force to convey the sewage. Moreover, instead of taking the waste only to the Magnan stream, it is proposed to run it all the way down to the mouths of the Var River. This is a distance of some four miles, and while it is, of course, a safer plan, it would entail a very large expenditure of money, and occupy much more time in construction. Besides all this, it is no secret that sewage-pumps are apt to get out of order, and cause dangerous obstructions.

While readily admitting the engineering capacity of the French, I have urged the authorities, in their own interest, to obtain at least the approval for their new plans of some English expert, like Sir Douglas Galton. The Mayor of Nice, quite alive to the benefits likely to arise from satisfying the wealthy Anglo-American contingent, has expressed his entire willingness to obtain the approval of the Municipal Council for such a course. Florence having already taken this step, it is more than likely that Nice will now do likewise.

It is satisfactory to know that all the old Nice culverts are soon to be replaced by a simple, cheap, and effective device, adapted by M. Bérard.

The climatic peculiarities of the Riviera invite sudden chills and colds, certain throat troubles, and an exacerbation of some nervous symptoms. But beyond that, all the evil that has been laid at the door of Nice, on the score of its dangerous climate, has been dictated by ignorance, envy, or malevolence. It must stand to reason that a place highly prized by the Romans for its sunshine and dry air, and which for centuries has maintained an excellent reputation as a winter health-resort for all classes of patients, cannot be devoid of substantial and permanent advantages. Volumes have been written on the climate of the Riviera. Nice enjoys nothing more nor less than Riviera climate. It is more sheltered than some places, but it is nevertheless exposed to the mistral, which blows at Nice just as it blows at other Riviera spots. It should be borne in mind by invalids and tourists, that Nice and the Riviera in general really possess two distinct and different climates, viz., a sea-shore or marine climate, and an inland or mountain climate. It is quite well known that immediate proximity to the sea may induce sleeplessness and other symptoms, denoting too exciting an action on the nervous system. The dry, sunny, inland air is tonic and sedative; the air along the shores of the sea is bracing and exciting. The air of the city itself is often a mixture of the two. There is the whole situation in a nutshell, and everything else is rubbish or *réclame*. One need not, therefore, be a physician to understand why Nice will benefit some patients and injure others.

For thermometric range and other meteorological data, consult special works, although they teach one nothing new.

At the present time Nice is not exempt from influenza, and catarrhal affections are quite plentiful. But a careful scrutiny of the causes of death, as well as conversation with leading practitioners and residents at Nice, have convinced me that there is no typhoid fever at present in Nice. Moreover, even should this dreaded disease exist in the dirty old Riquier quarter, there is no reason why the foreign colony should not remain exempt, owing to the impossibility of fouling the drinking-water. But, of course, it is always safer to have no fever within the city limits, as has been the case at Nice for some time.

There is no end of baths, massage places, and other so-called medical institutions at Nice. They are neither above nor below the standard of that class of establishments. Physicians will do well to investigate before allowing their patients to receive alleged treatment.

The Hammam de Nice is a Turkish bathing establishment, where the massage you get is very much better than the air you breathe. The director is a medical gentleman of skill and experience. It is a pity that he has not yet adopted Anglo-American ideas of ventilation.

There is also an English nursing agency at Nice, where trained nurses can be found. It was founded by Mrs. Hollond, and is known as the Hollond Nursing Institution. The directress is Miss Woodcock, 18 rue Paganini. The whole Riviera is supplied from here.

Nice has one medical society, called the Société de Médecine et de Climatologie. Under the auspices of this society, the monthly *Nice Médical* is published. Dr. Bonnal is the editor of this journal.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 5, 1892.

	Cases.	Deaths.
Typhus fever	30	2
Typhoid fever	10	3
Scarlet fever	224	37
Cerebro-spinal meningitis	2	7
Measles	366	14
Diphtheria	114	35
Small-pox	9	1
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

The Trans-Pecos Country as a Winter Health-resort for Consumptives.—According to Dr. Yandell (*Texas Sanitarian*), there is a portion of Northwestern Texas, formerly included in New Mexico, that has remarkable climatic advantages. It is called the Trans-Pecos country, and lies between the Pecos River on the east and the Rio Grande on the west and south, embracing the three counties of Pecos, Presidio, and El Paso. The conclusions of Dr. Yandell are based on the returns of the Signal Service, from the stations of Fort Stockton, Fort Davis, and Fort Bliss (El Paso), and from the reports of army surgeons and his own experience. The elevations assayed from 3,764 (El Paso) to 4,954 (Fort Stockton); the relative humidity from 47 in El Paso to 56 in Fort Stockton. While it is true that this territory does not possess an equable climate, it is claimed that the range *per diem*, which is from eighteen to twenty degrees, is not disagreeable, but pleasant even for an invalid. A climate with slight range of temperature indicates humidity, while all high and dry localities have a decided diurnal range of temperature. The change from the warmth of the afternoon to the coldness of the night, and from the coolness of the early morning to the warmth of midday, are not sudden and are agreeable. They belong to a sunshiny climate, especially to this region where there are not more than two or three cloudy days in a month. Protected by the Rocky Mountains, the Trans-Pecos country does not suffer from "northers," and high winds of any kind are rare.

It is held that Colorado and Northern New Mexico are

too cold for invalids. According to official figures taken from the records of the Health Office in El Paso, no white child has ever developed phthisis there, and only two adults since 1882. In one of these the phthisis was syphilitic, a common form among the Mexican population. Several negroes, however, are supposed to have died of tuberculous phthisis during that time, but on the whole it is claimed that this region has no equal in the world as a winter-resort for consumptives, especially during the season from October 1st to May 1st.

An Epitaph on Tuberculin.—Under this title our esteemed contemporary, the *Medical Press*, speaks, we think, a little too severely of tuberculin and its discoverer as follows: "For those whose interest in Koch's remedy for phthisis is not wholly dead the recent numbers of *Riforma Medica* contain instructive reading in the communication of Professor Rienzi to the Medical Academy of Naples. Like his brethren throughout the world, the professor hailed the prospect of curing, or staying phthisis, and hoping against hope, and with a faith strong in the face of the most startling facts, he determined to fairly test the remedy. He had the unfavorable reports of the medical journals throughout the world, and all the varying opinions of those who condemned and those who believed in the 'cure.' He had all the hints as to the selection of suitable cases, and he took every care to produce a favorable result. Forty-four patients, full of faith and hope, submitted themselves to the hypodermic injections, of which 469 were given. The number was quite sufficient to satisfy the professor. Two patients died suddenly of pulmonary œdema, and 13 of them were made very much worse. Of the whole 44 patients not one was benefited. Four of them, however, thought they were improved. There is no need to sound any note of warning against the use of the Koch nostrum—it is dead—no galvanism can even produce a semblance of life in its corpse. The most Teutonphile is ashamed of the utter collapse of the German fraud. £16 an ounce for spoilt glycerine, which only caused blood-poisoning, could not be defended on the grounds that the vendor was a scientist whose sole aim was medical progress. The terrible injury not alone to medicine, but to the people, of the countenance of Koch's secret remedy, will, we sincerely trust, be a lesson to all members of the medical profession. Medicine has nothing to do with secret nostrums, no matter how distinguished the vendor. Is it an adherence to the study of nature to blindly accept authority and use a drug of which nothing is known except that the sale makes the seller a rich man? When a physician vends a quack remedy he has by the act left the ranks of the profession, and joined the ranks of quackery, and stands in line with Holloway, Seigel, and Sequah."

The Suppurative Process.—At the recent meeting of the Pathological Society of London, Mr. Shattock read a paper in which he urged a revision of the terms at present employed in connection with the suppurative process. He maintained that the terms "suppuration" and "pus" were purely anatomical, and that they included things quite different in their etiology. Setting aside larger questions, the process of acute suppuration could etiologically be distinguished from other forms, and it was now well established by experiment that it was as specific in nature as tuberculosis or syphilis. Koch's four postulates in this case were all capable of fulfilment while the doctrine was confirmed by the check experiments of introducing aseptic chemical irritants beneath the skin of animals; if the animals were healthy, these produced inflammation but not suppuration. A strict parallel might be drawn between tuberculosis in its different manifestations and acute suppuration. Thus tuberculosis might be local, and there were local forms of acute suppuration, viz, acute circumscribed abscess, and diffuse suppuration; glandular tuberculosis corresponded with glandular abscess; general tuberculosis was analogous to pyæmia. The author suggested the term "pyosis." The acute abscess or acute suppuration of a wound would be pyosis in a local form, the secondary glandular infections would be termed glandular pyosis, and pyæmia be generalized pyosis. Mr. Shattock then mentioned some observations which he had made on the presence of peptone in the pus of acute abscess. The best method of demonstrating its presence, he said, was to shake the pus with half its bulk, or less, of a saturated solution of ammonium sulphate and then add crystals of the same sort to saturation. Filter. If a drop of copper-sulphate solution were then added to the clear filtrate no precipitate would be produced, for the ammonium sulphate had precipitated all the proteids except peptone; a dense white precipitate of potassium sulphate would be thrown down on adding excess of solution of caustic potash. On this subsiding the pink coloration of the supernatant fluid could be seen. He had been able, by dialysing pus, to show the same with the biuret reaction. For the separation of the albumoses, Dr. Sidney Martin's method was necessary. The presence of albumose and peptone in pus was not peculiar to the action of pyogenic microbes. Dr. Martin had shown both in the alkali albumin in which he had grown bacillus anthracis. Dr. Hunter said the peptone was undoubtedly formed by the agency of the organisms in the pus, and it was possible to give even a clearer demonstration of this fact, for if the ferments were isolated from the organisms they would still form peptones in albuminous fluids. This explained the occurrence of localized or diffuse inflammation after primary infection. If the organism were one which gave rise to a ferment of great peptonizing power, then the tissues would undergo rapid solution, and the lymphatics being quickly blocked the inflammation would remain localized; if, on the other hand, the organism produced a ferment of low peptonizing power, there was but little solution of tissue, the lymphatics remained open, and the inflammation spread. Dr. Lee Dickinson said he had examined several specimens of pus from pleural empyemata, and had always found the albumose to be more abundant than the peptone—possibly because the peptone was more rapidly absorbed from the pleura. Dr. Martin had found very little peptone in the fluid in which anthrax bacilli had been cultivated. Mr. Shattock in reply said the amount of peptone in all his specimens was very small—a mere trace, and the amount of albumose much larger.

Russian Universities.—The total number of students in the University of Warsaw during the current semester is 1,189, of whom 621 belong to the medical faculty. In the University of Dorpat the total number of students on September 1, 1891, was 1,723, of whom 863 were students of medicine. Between February 1st and September 1st the number of diplomas granted by the Medical Faculty of the University was 218. The degree of Doctor of Medicine was conferred on 46 candidates; the simple *venia practicandi* was granted to 39; the title of "District Medical Officer" to 14; the degree of Master of Pharmacy on 5; licenses to dispense to 32; licenses as druggists' assistants to 49; licenses to practise dentistry on 15; licenses to practise as midwives were also granted to 13 women. The number of students in the University of Kasan during the academic year 1890–91 was 757, of whom 402 belonged to the medical faculty. The degree of Doctor of Medicine was conferred on 5 candidates In the Military Medical Academy of St. Petersburg the license to practise was granted in 1891 to 100 candidates, of whom 38 passed "*cum laude*." Kieff licensed 72 candidates.—*British Medical Journal.*

Picrotoxine has been found by Murell to be an excellent remedy for night-sweats, in dose of one milligramme. It is supposed to act on the respiratory centres. Though its action on the perspiration is like that of atropine, it is indeed an antidote to this drug, as well as to hydrate of chloral.

A Suggestion with Regard to Spraying the Nasal Cavities.—Dr. F. A. Burrall, of New York City, writes: "As an aid to thorough spraying of the nares, I have formulated the following method, which originated from a suggestion made to me by a patient on whose nasal cavity I was using the upward spray: Direct the patient to inhale deeply, and place the tip of the atomizer behind the uvula without touching the posterior pharyngeal wall. Then the patient is to close his lips upon the tube and exhale through the nose. This carries the spray well forward upon the walls of the nasal cavities, and when an oily solution is used, such as the extract of pine needles in benzoinol, the volume of spray issuing from the nose resembles that of the air from the nostrils on a frosty morning. This process makes the spraying of the posterior and anterior nasal cavities more thorough than can be done by an ordinary application. It is a method worth mentioning, as there may be some physicians to whom the idea has not occurred, and they will find it serviceable."

A New Vegetable Digestant.—A digestive ferment has been isolated from the milk-juice of the Brazilian white fig tree (*Urostigma Dolarium*) by Peckolt. The milk-juice of this tree is of a creamy consistency, has an almond like flavor, and readily dissolves fibrin and coagulated egg albumin. In addition to this ferment the juice contains caoutchouc and a principle named dolarlin, which, it is claimed, has tænicide properties.—*Meyer Brothers' Druggist.*

Cigarette Smoking.—The United States use 2,400,000,000 per year, or about 68 for each of the adult population, or 100 for each male. Russia consumes 2,593,000,000; Austria, 1,980,000,000. French smokers consume 10,000,000 francs worth of cigarettes every year; 1,500,000,000 are smoked every year in Great Britain and Ireland, London alone using up 1,000,000 a day.

The Man Has Been Found who established the first dispensary. His name was Théophraste Renandot. And now it is proposed to erect a monument to his memory. Never!

Physiology in 1891.—The *British Medical Journal*, January 2, 1891, speaks of the progress of physiological investigations last year. The discoveries have not been particularly new and striking, yet there has been a steady advance everywhere in knowledge. The related questions of phagocytosis, protective proteids, and poisonous albuminoses have been laboriously worked out and are somewhat nearer elucidation. Heidenhain's work on lymph, the *Journal* suggests, is perhaps the most remarkable and interesting paper of the year. Absorption of products of digestion is not merely osmosis. Exudation of lymph cannot be explained simply as due to diffusion under pressure. Heidenhain shows that it is dependent on the secretory activity of the endothelial cells in the capillary walls. The distinction between blood lymph and tissue-lymph, upon which he also lays stress, affords a newer view to those who have always considered all kinds of lymph as exudations of blood-plasma. Another subject of physiological interest is the important part played by calcium salts in the various processes of coagulation. This line of inquiry has been carefully pursued by Ringer, Wright, and Sainsbury, in England, and by Arthus and Pagès, in France. Among important researches in the physiology of the nervous system, Ramon y Cajal and Kölliker, after methods introduced by Golgi, have succeeded in more fully demonstrating the non-continuity of sensory nerve-fibres with nerve-cells. Nervous impulses must therefore pass by virtue of mere contact, instead of through anatomically continuous channels to the cells. Nothing definite is yet advanced in regard to the true explanation of the connection between pancreatic disease or extirpation and diabetes. The pancreas is not a mere manufactory of pancreatic juice. It also now appears that the kidney has other uses than the secretion of urine; or at least that it plays an important part in the metabolic cycle, just as the liver performs many important metabolic functions other than the secretion of bile.

A Recipe Returned from Over Sea.—It is reported that at the Manhattan Club in New York a warm beverage, called an "oyster cocktail," is largely dispensed. For the benefit of those who may be possessed of suicidal intentions, I give the recipe. Seven small oysters are dropped into a tumbler, to which must be added a pinch of salt, three drops of fiery Tobasco sauce, three drops of Mexican Chili pepper sauce, and a spoonful of lemon juice. To this mixture add a little horseradish and green pepper sauce, African pepper ketchup, black pepper, and fill up with tomato juice. This should be stirred with a spoon, very slightly crushing the oysters, which are then lifted out and eaten, the liquid following as a cocktail.—*Hospital Gazette.*

How to Rid a House of Fleas.—A correspondent of the Washington *Star* says that he completely rid a badly infested house of fleas in two nights by a very simple procedure. He placed sheets of sticky fly paper on the floors of the several rooms, each sheet having a piece of fresh meat in the centre. The fleas jump for the meat and fasten themselves to the paper. If New York is visited the coming summer as it was the last, this will be a point worth remembering.

The Cause of Baldness, says a recent German writer, is too much barbering. In support of his theory he instances long-haired artists who never trouble the barber and have a plentiful stock of hair, but he forgets that such people are usually killed off by an outraged populace before they get old enough to be bald.

Mandibular Tubercles.—At a meeting of the Pathological Society of London, Mr. Bland Sutton described four cases illustrative of the mandibular tubercle which is occasionally found in one or both cheeks of children, at a point from two to four centimetres behind the angle of the mouth. In three of the cases there was a distinct cicatrix in the buccal mucous membrane opposite to the tubercle. One of the tubercles, on microscopical examination, presented the structure of a small dermoid.—*British Medical Journal.*

The Treatment of Tachycardia. — Dr. Poulet, of Plancher-les-Mines, has recently found a remedy for paroxysmal tachycardia, in a little known plant indigenous to Alsace, which appears to exert a rapid and beneficial influence over the paroxysms. The plant in question is the Coronilla varia, or *faucille*, which, like some other species of Coronilla, is sometimes used as a household remedy, being considered to have cathartic and diuretic properties. Some recent researches by MM. Spillmann and Haushalter on a closely allied species—Coronilla scorpioides—showed that that plant acts as a powerful heart tonic, causing an increase in the arterial tension and in the fulness of the pulse, exciting diuresis and diminishing œdema and dyspnœa—acting, in fact, very similarly to digitalis. Dr. Paulet was induced by these researches to make trial of Coronilla varia in heart cases. He employs a tincture made from the entire plant (1 in 5), also a powder made from the flower. The dose per diem of the tincture is from half a drachm to a drachm, and that of the powder from fifteen to thirty grains. These preparations, though they have a strong characteristic odor, are not nearly so disagreeable to the taste as those of Coronilla scorpioides. Details are given of two very severe cases in which these preparations of the Coronilla varia gave almost immediate relief. M. Poulet recommends this drug also in other heart cases where digitalis has been used, and where it seems to have been given for too long a period, or, as sometimes occurs, where it has begun to act on the gastro-intestinal canal.—*The Lancet.*

THE NATURE AND FREQUENCY OF INEBRIETY, WITH REMARKS ON ITS TREATMENT.[1]

By CHARLES L. DANA, A.M., M.D.,

NEW YORK.

VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

IN the past year there has been an enormous interest shown in the subject of inebriety, especially in lay circles and in the public press. This interest has centred upon two things—the treatment of inebriates and the question of the physical basis of drunkenness and intemperance. The view that these conditions are the expression of a disease has been exploited without contradiction until the public has perhaps begun to believe that alcoholic indulgence is always something of which persons are simply the unfortunate and irresponsible victims.

The purpose of this paper is to make a brief contribution to the subject of the nature and characteristics of inebriety as distinguished from drunkenness, and to its frequency, to which I shall add a few words on the subject of treatment. My remarks will be based largely on a study of the cases of alcoholism, in all its forms, which are brought to Bellevue Hospital, numbering nearly four thousand yearly. Three years ago I made a clinical analysis of the cases, which entered the hospital in 1889.[2]

Recently I have made a study of 614 cases of male alcoholics entered in the last part of the year 1891. In these latter observations I made particular inquiries as to the drinking habits and ancestry of the patients. These cases represent persons from all walks in life, the proportion being about as follows:

	Per cent.
Professions	3
Clerks	15
Tradesmen	25
Laborers	35
Drivers	8
Others	17

There is some preponderance naturally of the lower and laboring classes, yet the list of occupations includes many persons in all walks of life, and the analysis corresponds in most respects to that made by Dr. Mason of inebriates at Fort Hamilton. The observations made upon them have therefore, I believe, value as a social and pathological study.

I shall discuss now only the male cases, as it is concerning their histories that my inquiries have lately been directed. They make up about three fourths of the total. About one-half are in a condition of plain drunkenness. From this they usually recover in a day or two, are discharged, and sometimes return again in a few weeks or months. If they return often they receive the name of "rounders" and "bums." The other half consists of persons who are verging on, or already in, delirium tremens, or in alcoholic coma, convulsions, or mania. The patients are classified therefore as—1, plain "drunks;" 2, delirium tremens; 3, febrile delirium tremens; 4, mania a potu; 5, miscellaneous and complicated cases. About ten per cent. die either from a complicating pneumonia, from delirium and exhaustion, or meningitis. A smaller per cent. becomes insane. The most frequent complicating condition is epileptic convulsions. Among 350 there were 11 cases, or over three per cent. Next comes insanity or dementia, two per cent. Phthisis and nephritis were found in 5 and 2 cases, respectively, out of 350. Rheumatism occurred in 2 cases. Multiple neuritis occurs in about 1 in 400 or 500 cases of men; very much oftener in women—one or two per cent. Drinking habits in the parents were reported in all but 10 out of 350. Usually the father is the drinker; in 8 cases both parents; in 1 case the mother alone. The age, sex, race, and occupation I have given in a previous study.

The question that has often presented itself was, How many of these persons who were brought to the hospital suffering from acute alcoholic intoxication were victims of the disease, so called, of inebriety?

I have spoken of inebriety as a "so-called" disease not because I doubt its existence but because, as the word is often used, it includes a vast number of cases that belong to social and moral reformers, not to physicians alone.

In a work on inebriety by Dr. Norman Kerns we are told that no disease is more common than that of which he writes, and that there are but few families in which some member is not a victim. Inebriety, according to the same author, is a disease characterized by an overwhelming desire to get drunk. He seems to include nearly every person who drinks, and at times gets drunk, in this class, and the ordinary lesions of chronic alcoholism are spoken of as being the pathological basis of the disease. I cannot agree with such sweeping statements or such comprehensive definitions.

It is impossible, to be sure, to define inebriety with precision or to establish arbitrarily its exact characteristics. But it is, I believe, the wiser and safer course to limit as much as possible the class of cases to be placed in this category. For we know, in the first place, that inebriety, however loosely defined, is not a disease which has a structural or anatomical basis that can be recognized. We know that it is a symptom only of psychopathic and neurasthenic states. The lesions found in chronic inebriates are the consequence, not the cause, of their indulgence. Neither inebriety nor drunkenness is ever, strictly speaking, a disease. It is a symptom only. It is a symptom, on the one hand, of a degenerative nervous system or of an acquired neuropathic state, and, on the other hand, of a weak, self-indulgent, and perhaps depraved character. Between these extremes there are all sorts of gradations. But most habitual drunkards are much nearer the class of those who are weak and self-indulgent in character than of those who drink from the impelling force of a morbid craving

In a certain sense, and taking a purely material standpoint, criminals, sensualists, libertines, drunkards, are all the victims of a disease, *i.e.*, of a constitution and personality which are abnormal. But neither pathology nor economics is yet ready to adopt this view. We still consider disease to be a disorder of the body and its organs; vice to be a disorder of the character, for which the individual must be held responsible. When a man has a depression of spirits, gets nervous and worried, takes to drink, and drinks steadily, more and more, till he makes a wreck of himself, it seems to be the custom of the propagandists of the gospel of inebriety to say that he has caught their disease. But this may not be so. If it were morphine instead of alcohol, we should say that the patient had a morbid habit or craving, not that he had got a disease. We are told, again, that neurasthenia

[1] Read at a meeting of the New York Academy of Medicine, Section on Public Health, February 17, 1892.

[2] New York Medical Journal, June 14, 1890.

causes inebriety, that fracture of the skull, blows on the head, and stricture of the urethra do the same.

This is a loose way of dealing with the subject. Trauma, shocks, and local diseases, we know, cause neurasthenic states, and a craving for drink, or for women, or tobacco, or candy, may be one of the symptoms thereof. But the craving is only a part of the symptoms.

I say again, then, that we ought to limit the application of the word inebriety, for the present, as rigidly as possible.

I should define inebriety as a periodical psychosis characterized by attacks of uncontrollable craving for drink, the craving being for quantity not for quality, and the patient being perfectly or relatively abstinent between his seizures. Inebriety is a periodical convulsive or fulminating psychosis, a form of instinctive insanity. Besides this typical form there is another, allied to it. In this the patient, who is neurasthenic and melancholic, takes liquor for the purpose of drowning his discomforts and cares. The first drink paralyzes his will, excites the drink instinct, and he takes another and another. He cannot stop himself, and he plunges into a prolonged debauch. After recovering from it he remains temperate until another period of temptation occurs. He cannot drink temperately at any time, because a small dose of liquor flies to his head or disturbs his stomach; hence he abstains except when his periods of depression occur. Here the periodical indulgence is much more truly symptomatic of a neurasthenic state than is the former type.

Of course there are cases which shade from the foregoing types into those of common drunkenness; but I think that the above classification is as nearly accurate as is at present possible.

The so-called habitual inebriates who drink and keep more or less drunken the whole year through should be classed as persons who have depraved and morbid habits, with, in many cases, the secondary diseases which are the result, not the cause, of their indulgence in liquor.

Among 350 cases whose histories I have especially studied the following is a fairly accurate analysis:

Steady drinkers	261
Sots	15
Occasional drinkers	25
Periodical inebriates	18
Unknown	31
Total	350

By the steady drinkers I mean a class of persons who drink every day whenever occasion offers. They get drunk, as a rule, deliberately on holidays, and Saturdays or Sundays. The sots, or as they are technically known to hospital attendants, the "bums," are persons who keep themselves continuously as drunk as their means and work allow.

The proportion of persons who are, strictly speaking, inebriates is thus seen to be about five per cent. This estimate is not too low, for the patients are rather inclined to make as good a story as possible of their habits.[1]

When it is remembered that besides the 4,000 alcoholic cases taken in yearly at Bellevue, there are about thirty thousand cases of plain drunkenness brought yearly to the station houses, it will be seen that the inebriate psychosis is really a very rare one, and that plain *drunkenness is to inebriety about as* 700 *to* 1.

This conclusion is, I believe, borne out by the personal experience of physicians, although we, as a class, are brought professionally into relation chiefly with the inebriate and insane alcoholics.

The vast majority of excessive drinkers then, are, I believe, persons who have gradually acquired a taste for alcohol, or who resort to it more or less deliberately for purposes of conviviality, and to drown the cares and sorrows of an uncomfortable environment.

[1] I am very greatly indebted to Mr. Monell, the attendant in charge of the Bellevue cells, for his industry and care in helping me to secure data for this paper.

Treatment.—In dealing therapeutically with alcoholic indulgence, therefore, we should be careful to estimate to what extent this indulgence is a morbid habit, and to what extent it expresses a degenerative psychopathic disease.

In all cases self restraint and removal of bad influences is an important factor; but in the rare psychosis of inebriety good resolutions are of little avail and medical treatment is imperative. In the common chronic alcoholic states the "mind-cure" and isolation are vastly more important factors. I do not deny that in most of these cases the bodily system has undergone a change by reason of its excessive and constant poisoning by alcohol. The nutrition of the nervous system is so perverted that it requires for its comfortable action the presence of alcohol. This change of nutrition might be looked upon strictly as a disease, but it has this peculiarity that by an effort of the mind the craving can be made eventually to disappear. We cannot will away the true neuroses, like epilepsy, chorea, neuralgia, and functional spasms, or the true psychosis, like mania. Furthermore, if such acquired appetites are to be regarded simply as pathological, then we must add to our list of diseases the craving for pie, the habit of chewing gum, of eating candy, of taking an egg for breakfast, without regular indulgence in which some people would feel most uncomfortable.

Nothing, it seems to me, is more unscientific than to pronounce as inebriety all the curious mental disorders and nervous phenomena caused by a few drinks of liquor. A man may have epilepsy, insanity, neuralgia, trance states A drink of liquor brings out these symptoms, but he is not, for all that, a sufferer from inebriety. That is only one symptom of many.

A few words further in regard to treatment. The suggestive treatment, and hypnotism, including the much-lauded Keely cure, do not and cannot cure true inebriety of the types described. This has to be treated as one would treat any degenerative psychosis. All forms of tonic treatment, the water-cure, electricity, pure air, good food, removal from any depressing or irritating surroundings, are indicated here. There is one drug which has been long known to have a certain degree of specific effect in inebriety and in alcoholic intoxication. This is strychnia. Its use both in acute and chronic alcoholism is undoubtedly attended with good results. In acute alcoholism, when the system is overwhelmed with the poison, it is my custom to give it in doses of gr. $\frac{1}{60}$ every two or three hours.

In chronic alcoholism and in inebriety it should be given in good doses for a considerable time.

I am told that strychnia is really the basis of the Keely cure, and I presume that this drug, together with the moral influences, have done all that really has been done by the mythical gold injections.

In acute alcoholism my experience has covered a wide range of therapeutic endeavor. The old opium treatment was supplanted years ago by the use of bromide and chloral. This in turn was followed by the use of hyoscyamin (often with deadly effect) and morphine, and of the newer hypnotics, such as paraldehyde, sulphonal, etc.

As the result of a good deal of experience I have come to the conclusion that, in ordinary acute delirium of alcoholism, chloral in large doses (gr. xx. to xl.) repeated in smaller doses in two or three hours, and combined with digitalis and strychnia, is the safest and surest means of controlling the excitement and securing sleep.

This formula may be used.

℞ Chloral hydrat. ..... ℈ xvj.
Ext. digital. fl. ..... ♏ xlv.
Strychniæ nitrat ..... gr. ½.
Aquæ ..... ℥ iv.

M. Sig.: Dose ℥ ij. to ℥ iv., repeated in smaller amount every two hours if needed.

Such treatment is of course combined with a preliminary laxative, and with careful diet of hot milk and beef-tea with red pepper.

In febrile delirium tremens depressants must be used with care, and strychnia given hypodermically every three hours. Cold baths or cold wet packs, with friction, must be applied every two or three hours while the temperature remains high.

The use of hypodermic injections of morphia is very rarely needed, and I do not advise it. The use of hyoscine and hyoscyamine is, in my opinion, positively unjustifiable except in mania a potu. Here there is a mental disease, not an intoxication with alcohol, and a paralyzing drug like hyoscyamus may be safe.

In conclusion, I would restate the points I desire to make, as follows: Inebriety is never, strictly speaking, a disease. It is a symptom of a neuropathic or psychopathic constitution, and is usually only one of numerous other symptoms. In its most common and its typical form it is a periodical psychosis.

Of the enormous number of persons who drink intemperately a very small proportion are strictly inebriates. In this city there are at a rough estimate seven hundred drunkards to one inebriate. Of the cases brought to Bellevue about five per cent. are inebriates. Inebriate specialists see more, relatively, of true inebriety. In large general hospitals the percentage is nearer the normal, and a better point of view is gained. Inebriety is a rare disease relatively. It is but slightly amenable to moral influences, hypnotism, or suggestion, and is not at all affected by chloride of gold or any specific medicine. It is helped by suitable general treatment. Habitual drunkenness, like other bad habits and morbid cravings, is helped by moral influences, self-restraint, as well as by proper medical treatment. The results of treatment at Homes, where restraint and moral influences are chiefly applied, are apparently as good as those where all forms of alcoholic indulgence are looked upon and treated as a disease.

REPORT OF A CASE OF COMPLETE NON-MENSTRUATION.[1]

By HUBBARD WINSLOW MITCHELL, M.D.,

NEW YORK.

The subject of this sketch, Miss E. F——, is a young unmarried woman, twenty-four years of age. She was born in Ireland, and, until her emigration, lived quietly at home with her parents. In March, 1888, being then twenty years of age, she left home and came to this city. Up to that time no signs of menstruation had appeared, and, as she tells me, she had never heard that such a function existed. Her mother had never enlightened her upon this point. Soon after her arrival in New York she obtained a situation as a waiting-maid, and her fellow-servants in the house where she lived, and also her sister in law, noticed after a time that she was not unwell at each month. Like all uneducated persons, these friends filled her ears with wild stories about the dreadful effects likely to follow the absence of menstruation, and she was told that she would eventually become insane. This worried her greatly, and as a consequence she became pale and anæmic, with loss of flesh, appetite, and sleep, and she suffered from a long train of imaginary nervous symptoms.

On April 7, 1889, she presented herself to me for treatment, and I found her in the above condition. She insisted upon a uterine examination. This was made, but revealed no pathological condition of her uterus. She was told to pay no attention to the fact that she had never menstruated, and upon my assurance that she would not die, or become insane, nor a chronic invalid, she soon forgot that she differed in any way from other girls.

A course of chalybeate tonics, generous diet, and proper care of her general health soon restored her to her normal condition, and she has remained ever since a perfectly healthy girl. She has been under my close observation ever since she first consulted me, in April, 1889.

In January of the present year she submitted to a thorough examination, with the view of having her case reported in this paper, although she was entirely free from any abnormal symptoms. The examination revealed the following facts, touching her physical condition:

Weight, 105 pounds (her weight before leaving Ireland was 130); girth of chest, twenty-nine and a half inches; girth of abdomen, twenty-five inches; girth of pelvis, thirty-four and a half inches; girth of thigh, upper-third, twenty inches; heart healthy, sounds and rhythm perfectly normal; pulse, 76; lungs healthy, respiratory murmur clear and distinct over every part, respiration easy, and twenty per minute; the mammæ are well developed, firm, and round, nipples small, no areola; her skin is soft, smooth, and healthy; figure erect, plump, and symmetrical; her bowels are regular; kidneys, healthy. She has a good appetite, sleeps well, and in no particular shows any sign of ill health.

The uterine examination reveals a short vagina, and a small, round cervix uteri, rather less in size than the average, and projects very slightly into the vaginal canal. Depth of uterus from os to fundus, two and a quarter inches. This would show that the organ is very nearly normal in size. Of course, no examination of the ovaries could be made, but there is no external sign of abnormality present. This examination shows that she is a well-developed healthy young woman, performing all her physiological functions naturally and regularly, except the single function of menstruation. It might be asked, Is there not a vicarious menstruation to take the place of the natural function? There is not. I have watched her very closely during the past two years, and have not detected the slightest disturbance of the symptom, nor the least periodical excitement. Hence it is safe to say that the physiological function of menstruation is totally absent in this girl.

The essential part of the menstrual function is a growth and maturity of the ovum or egg, in the Graafian follicle of the ovary, occurring at regular and stated intervals, and the discharge of this egg from the ovary. When the egg is fully matured by a process of physiological growth in the ovary, the thin and weakened walls of the Graafian vesicle, with its superjacent covering, are ruptured and the ovum passes, with its serum and blood, into the fimbriated extremity of the Fallopian tube. Here the peristaltic action of the tube, and the vibratile movements of its lining cilia convey the delicate ovum in safety to the cavity of the uterus. This is a physiological function of menstruation or ovulation, as it appears in its normal condition, and renders the female capable of the function of reproduction.

The secondary process of reproduction of the egg after it has found its way into the uterine cavity is quite independent of menstruation. Upon reaching the cavity of the uterus it remains for a time awaiting impregnation through the sexual congress of the male, if this does not take place the egg soon loses its vitality, and is conveyed away from the uterus by its secretions. This process of menstruation is the natural and usually the only one observed in the human female, occurring in her generally once every four weeks, and this periodical occurrence may be taken as evidence that the ovaries are in a condition of healthy activity, and renders her capable of the function of maternity and propagation.

In the lower animals forming the great and important order of viviparous mammalia the reproductive function is the same, and depends for its fulfilment, on the part of the female, of the production of an egg in the special follicle of the ovary, and its subsequent discharge therefrom. This discharge of the egg from the ovary in

[1] Read before the New York County Medical Society, February, 22, 1892.

these animals is accompanied by a peculiar condition of excitement known as "heat," "rutting," "œstruation," with more or less flow of blood. This condition is seen in such animals as the rabbit, dog, and cow, and also in the lower apes, or the cynomorpha, and especially in the higher apes or anthropomorpha. Among these last are the lemurs, chimpanzees, orang-utans, and the gorilla. In these apes the function of œstruation proceeds with a physiological regularity. The period of ovulation in some of the lower animals, however, differs. In some it is short, and in others it occurs at longer intervals.

If we descend still lower in the animal scale, we also find that the production of an egg within the ovary, suitable for fecundation and reproduction, is the chief element in the physiological process of propagation. In birds, and the higher reptiles, such as the alligator, crocodile, turtle, and others, the egg is fecundated within the body of the female, and incubated externally to her body by the proper application of artificial heat. These animals usually lay their eggs in some suitable and sheltered place, and are hatched by the warmth of the sun. In fishes, which occupy a still lower plane in the animal scale, the eggs, which are produced by the female, are deposited in some place of safety, where they are visited by the male and duly fertilized, after which incubation takes place without further care from the female, and the young are then duly hatched. This is true also of frogs.

In all these forms of animal life, from man down to a fish, an egg must be produced by the female in organs adapted for that special work. It is this production of an egg in the ovary that constitutes her a normal animal, with normal and complete physiological functions.

Cases are on record where impregnation has taken place in the human female without menstruation ever having taken place, and even where the hymenal membrane was not ruptured; and cases are also on record of complete sterility where menstruation has occurred regularly, and apparently in a normal manner; but in all such cases it is extremely probable that the real cause of these abnormalities can be easily detected and traced to its exact origin if a careful examination is made of each special case. It is, however, rarely indeed that we have an opportunity of seeing a young and perfectly healthy woman, normal in every function, but in whom there is a total absence of all the phenomena belonging to that special function of menstruation. In the present case this function has remained perfectly dormant from the period when puberty usually occurs to the present time.

The question may be raised, Is this young woman like others of her sex, and having sexual instincts and desires? As far as is known these are entirely absent in her. The mons veneris is almost destitute of hair, and the labia are rather undeveloped. The clitoris is about normal.

A single and isolated case like the one under consideration is not sufficient to form a judgment of the effects of a total absence of menstruation, but it is extremely interesting as it shows that this peculiar function, usually considered so important and so essential to the health and well-being of an individual, may be totally wanting, and yet the woman enjoy in every other respect perfect and uninterrupted health.

747 Madison Avenue, February 22, 1892.

Congenital Peritonitis.—Dr. Anton Genersich, of Clausenburg, recently exhibited at a meeting of a Hungarian Pathological Society a case of peritonitis occurring in an infant which had doubtless originated from perforation of the small intestine before birth.

Salipyrin is a chemical compound of antipyrin and salicylic acid, 57.7 parts of the former to 42.3 of the latter. It occurs in the form of small colorless crystals, slightly soluble in water but freely so in alcohol, having a mildly astringent subacid taste. It is supposed to combine therapeutically the properties of its two component parts.

RECOVERY, WITHOUT SUPPURATION, FROM A COMPOUND DISLOCATION OF THE ANKLE, IN A PATIENT OF FORTY-FIVE.

By R. R. EGAN, M.D.,

Assistant Surgeon, United States Army.

The year 1861 marks the transition from septic to antiseptic surgery. Lister, in that year, began to cover wounds with lint steeped in carbolic acid. This was supplanted by the spray and protective. The spray in its turn was replaced by irrigation, with disinfectant solutions. In our day, irrigation is rapidly giving way to Arnold's steam sterilizer. Eulogy after eulogy has been heaped on Sir Joseph for the transformation, while the name of the great military hygienist, Parkes, has remained almost unnoticed. Yet it is difficult to say to whom "more than half" the credit belongs. The complicated system of Lister is fast being resolved into cleanliness and hygienic surroundings, for which Parkes always contended.

The "antiseptic system" was first introduced in the treatment of compound dislocations of the ankle-joint, at the Royal Infirmary, Edinburgh. Great advantages were claimed to follow its application. Suppuration was said to be prevented and the utility of the limb restored. By the older methods death was said to be common. In a lecture delivered February 14, 1870, Lister stated that Syme informed him that at one time, in looking up the hospital records, he found that the last fourteen cases of compound dislocation had ended fatally.[1] Syme's experience was, however, exceptional. In a large number of cases collected by Culbertson and Andrews,[2] the mortality under various modes of treatment was as follows: Syme's amputation—Cases, 325; died, 30; mortality, nine per cent. Pirogoff's amputation—Cases, 130; died, 24; mortality, eighteen per cent. Amputation lower third of leg (traumatic)—Cases, 148; died, 48; mortality, thirty-two per cent. Excision of ankle (not from gunshot)—Cases, 112; died, 19; mortality, twelve per cent. Dr. Andrews adds: "In ordinary practice the percentage of mortality will be found less than in the above statistics, which include a large number of cases from the hospitals of Vienna and Paris, where a fearful mortality accompanies all surgical operations."

Sir Astley Cooper, in pre-antiseptic days, gave forty-four recorded cases without a death.[3] Before the days of this great surgeon amputation was always performed for the accident. In his treatise on "Fracture and Dislocations"[4] he asks, "Is amputation generally necessary in compound dislocations of the ankle? My answer is, Certainly not. Thirty years ago it was the practice to amputate limbs for this accident; the operation was then thought absolutely necessary for the preservation of life by some of our best surgeons, but so many limbs have been saved of late years—indeed, I may say so great a majority of these cases exist—that such advice would now be considered not only injudicious, but cruel. It is far from being my intention to state that amputation is never required; I have only to observe that the operation is unnecessary in the greater number of these accidents." Further on he states: "From all I have seen I should not hesitate to advise the immediate removal of the limb where the lower heads of the tibia and fibula are very much shattered; where, together with the compound dislocation of these bones, some of the tarsal bones are dislocated and injured; where any large vessels are divided and cannot be secured without extensive enlargement of the wound and disturbance of the soft parts; where the common integuments with the neighboring tendons and muscles are considerably torn; where the constitution of the patient is enfeebled at the time of the accident, and not likely to endure pain, discharge, or long confinement."

[1] Lancet, July, 1870.
[2] International Encyclopædia of Surgery.
[3] Mr. Croly: New York Medical Journal, January 25, 1890.
[4] American edition, 1844.

But, as will be seen from the following, his resort in exceptional cases was not to amputation, but to incision of the ends of the bones: "If the dislocation can be easily reduced without sawing off the ends of the bone; if the bone be not so obliquely broken but that it remains firmly placed on the astragalus when reduced; if the end of the bone be not shattered (for then the small loose pieces of bone should be removed, and the surface of the bone be smoothed by the saw); if the patient be not excessively irritable so as to occasion the muscles to be thrown into violent spasmodic actions, by the attempts at reduction and which lead to subsequent displacement when the limb has been reduced; the bones should be at once returned to their places, and the parts should be united by the adhesive influence; but rather than amputate the limb, if the above circumstances were present, I should certainly saw off the ends of the bone."

His opinions are quoted at length, because they dominated over the medical world from 1820 to about 1850. They were followed by Malgaigne [1] and all the prominent surgeons on the Continent. Later we shall see that they still remain the recognized treatment at the present day. Between 1850 and 1860 Syme's love for the amputation which bears his name led him to apply its use to treatment of this injury. In his "Surgical Works," edited by Maclean,[2] he states: "Compound dislocation of the ankle-joint, either with or without that curious displacement of the astragalus which results from falling with great force on the heel, was formerly held to require amputation of the leg. The authority of Sir A. Cooper's experience encouraged attempts to preserve the limb in these cases; and in private practice both forms of the injury are now frequently conducted to a successful issue, though in general through a protracted process of recovery. But it must be admitted that many lives have been lost, especially in hospitals, from trying to retain the limb. In the Royal Infirmary I find that of thirteen patients who had suffered compound dislocation of the ankle, and were not subjected to amputation, only two recovered; and even in the event of recovery the foot generally remains in such a state of stiffness, weakness, and insensibility to external impressions, as to be rather an incumbrance than a support to the patient. Now all this danger, tedious confinement, and permanent discomfort might be obviated by amputating the foot in the first instance. So long as the only alternatives were an attempt to preserve the limb and amputation of the leg, there was a strong inducement to abstain from operation. But if the safety and speedy recovery of the parts may be insured by taking away merely the part of the limb which, in the circumstances, can be of little value, either as to use or ornament, while at the same time a stump is produced in all respects preferable to a shattered, stiff, irritable foot, I think there should be little hesitation in resorting to amputation at the ankle-joint under the circumstances in question."

The reaction led by Syme only obtained a partial sway over the minds of medical men. In very severe injuries they counselled amputation immediately performed for the safety of life and limb. In less violent injuries, with a sound constitution, they advised conservative surgery. If the bones could not be reduced without force, they deemed excision advisable. In this class stood Ferguson, Holthouse, Erichsen, and Gross. With the advent of antiseptics conservative surgery received a fresh impetus. Its status at the present day is fully illustrated by the recent contribution of Mr. Croly, of Dublin.[3] He treated conservatively a case of compound dislocation of the tibia and fibula forward on the dorsum, the entire front of the joint being laid open. Also a patient whose right tibia protruded three inches through the soft parts. At the same time the lower end of the fibula was comminuted and the foot forcibly everted. His third case sustained a compound dislocation of the tibia and fibula outward. All these recovered, with strong useful limbs, and sustained the opinion of Sir Astley Cooper "that amputation should not be performed in compound luxations of the ankle-joint." Excision should, he believes, be resorted to under the following exceptional conditions: First, where the bones are denuded, and there is difficulty in effecting reduction; second, where the fracture of the tibia is oblique, so as to be unable to rest on the astragalus; third, to relieve spasm of the muscles; fourth, to diminish local irritation and hasten cure.[1]

The following case came under observation soon after the appearance of Mr. Croly's communication:

S. S. B—— was admitted on the afternoon of March 18, 1891. The patient, a man of forty-five years of age, was engaged with several other men in pulling down some old buildings. He was inside one of the buildings removing a rafter from the roof, when, without any warning, the whole house collapsed, and fell in, throwing the patient to the ground. He was struck on the head and shoulders, a beam coming on the outer side of his leg (left). He was released as soon as possible and taken into the open air. He was found to have severe injury to his ankle, from which blood flowed freely. He was carried by the bystanders to a house and given some whiskey. There was no unconsciousness. A constricting band was placed above the ankle until my arrival.

When seen by me three hours later there had been considerable loss of blood, but his pulse was good. A wound of a little over three and one-half inches was found on the inner side of the left ankle, through which the tibia projected about one inch. The fibula was found fractured about three inches from the external malleolus. The foot turned outward at almost a right angle. When compression was removed, blood welled out freely. It was found that the tibia could be reduced and the foot brought into nearly its normal position. Although the patient declined to take ether or chloroform, reduction was effected. Pulsation was discovered in the artery at the external malleolus. The foot and leg were cleansed with a corrosive sublimate solution, 1 to 3,000 The tibia was reduced with a gush of blood from the joint; the foot was with difficulty held in place while a plaster-of-Paris bandage was applied as high as the knee over a layer of cotton wool. A compress of iodoform gauze was retained over the wound by the bottom of a large-sized bottle, while the plaster was applied round it. When the plaster was sufficiently hard, the bottle was withdrawn, leaving a window through which the wound could be dressed. No attempt was made at drainage, but an iodoform gauze compress was retained over the wound by a cotton bandage placed over that of the plaster of Paris. The leg was elevated on pillows. During the night enough of blood soaked through the compress to stain one of the pillows. A fresh compress was accordingly applied to the wound the following morning. A stain of blood appeared on the compress in the evening, but it was not deemed necessary to change it then. His temperature at 7 P.M. was 100° F. and his pulse 86. On the following two days the temperature was about 99° F. On March 22d it was normal, and continued so during the remainder of his treatment. The patient was, however, at times restless, and complained of pains during the night. On March 24th, as it was believed that some blood had infiltrated into the cotton wool and would undergo decomposition, the plaster splint was removed, fresh cotton applied, and the splint readjusted. The wound was found healthy, in good apposition, and without the sign of any discharge. It was covered with iodoform and dressed with sublimated gauze and a retaining cotton bandage. The patient remained in excellent condition. He was given one ounce of sherry before his breakfast and dinner, and a whiskey "nightcap" to insure sound sleep. Early in April the plaster splint showed signs of cracking. It was strengthened by three strips of iron and a fresh plaster

[1] Lancet, September 26, 1891.

roller. The part of the wound posterior to the malleolus was found to have healed. The portion over and anterior thereto was found covered with healthy granulations. From this period the wound was dressed once a week. There was no discharge at any time, save from the granulations, which became exuberant, and had to be touched with lunar caustic. About the 15th and 20th of the month the patient suffered from slight attacks of diarrhœa. Although these were believed to be due to errors in diet, yet it was deemed advisable to dress the wound with boric acid instead of iodoform. On May 10th the wound, save at one point, was healing under a crust. The plaster was accordingly removed and the patient allowed to go around on crutches. The foot could be freely flexed and extended. On assuming the erect position the limb became greatly swollen. Bandages were applied, but extreme difficulty was experienced in restoring the circulation. Notwithstanding every effort the wound again opened toward the end of May, as a result of this swelling. This accident retarded his progress, and confined him to bed for nearly a month. He was then fitted with an elastic stocking.

Early in September he passed from under observation. Although he had grown excessively stout he was able to walk very nicely with or without the aid of a cane.

The points of interest in the above case are, 1. The age of the patient—forty-five years. 2. The absence of suppuration. 3. The retention of mobility in the joint. 4. The absence of antiseptic irrigation or drainage-tubes in the treatment.

The object kept in view was to obtain union of the deeper parts of the wound as soon as possible. Corrosive solutions were thought to interfere with healing without suppuration. In the words of a recent writer,[1] "There is abundance of evidence to lead to the belief that normal tissues and fluids of the body possess the power of rendering inert many kinds of organisms which may have gained access to them. This function must, therefore, be diminished or destroyed by agents which bring about alterations in the constitution of these tissues. Such changes are known to follow the application of sublimate solutions, which may cause a condition of superficial necrosis by which the inroads of infectious organisms are not resisted, as they would have been had the tissues been left in their natural condition."

Had the interior of the joint been contaminated it would have been cleaned by the use of sterilized water.

A drainage-tube was deemed unadvisable on account of the fact that it gives rise to irritation like any other foreign body. When suppuration already exists, a drainage tube is a necessary surgical evil. In a clean, healthy wound there must be some special indication before it is used. As a routine practice, the introduction of a drainage tube always seemed to me unwarrantable. The following opinions of Park, which appeared since the above was written, seems especially worthy of consideration. He says, *loc. cit.*, "Our predecessors drained to permit escape of pus which they knew would form. Until lately we have drained to prevent its formation. We seem now to be on the eve of an era where we need to drain but little, or not at all. We resort to drainage now only of necessity in septic or infected cases. In other cases we drain mainly from habit or from fear. Indeed, when we start afresh, as it were, without previous infection, the practice of drainage is a confession of fear or of weakness, both of which are alike unscientific and unfortunate. We have learned that a little blood-serum is an advantage rather than a detriment, and we do not need to guard against its presence as we used to. It seems to me that in many cases, where all other aseptic requirements have been met, we do more harm than good by the use of drains."

Has the antiseptic system of Lister really improved the treatment of compound ankle dislocations? I am inclined to think not. The results of Sir A Cooper have not been surpassed, if they have been equalled, by any method of treatment yet invented. Emboldened by the real or supposed advantages of Listerism, surgeons have been disposed to trust more to conservative treatment, and the amputations of Syme have been discarded." But that the throwing into the joint of strong antiseptic solutions, which produce a certain amount of tissue-necrosis, while the edges are closed, and pressure made to force it into every cavity; that their application to the surrounding integument, where, as has recently been shown, micro-organisms are too deeply situated to be affected thereby; that, in fine, these procedures can prevent the occurrence of suppuration, is a subject on which there is room for a reasonable doubt

Lawson Tait needs only boiled water, a sewing needle, scalded silk, knives and catch forceps, cotton and boric acid to do an abdominal section.[1] To him we are specially indebted for perfect cleanliness of the wound, and to Edmund Parks for perfect hygienic surroundings. And is there aught besides?

Fort Warren, Mass.

Plants with Poisonous Odors.—There are few flowers whose perfume is actually deadly. It is said, however, that the flowers of the kali mujah, or death plant, found in the islands of Java and Sumatra, emit a perfume so powerful as to overcome, if inhaled for any length of time, a full-grown man, and killing all forms of insect life approaching it. This perfume resembles chloroform in the effect, producing insensibility. All insects and birds seem instinctively to avoid the plant. Linnæus mentions a case in which the odor of the rose bay proved fatal, and there is a plant known to the Persians as kerzereh, the perfume of which they believe will kill a man if he inhales it after a hot south wind has passed over its blossoms. Many other plants, though not having deadly perfumes, nevertheless give forth odors which are decidedly hurtful. The pœdaria fœtida excites fever and headaches in those inhaling it. One of the magnolias emits an odor which produces in many persons nausea and sickness, and the poison sumach and poison logwood are apt to lead to similarly unpleasant effects.—*Brooklyn Eagle.*

Is the Writer a Bald-head?—Dr. T. J. Hutton, of St. Paul, Minn., sends us the following on "The Philosophy of Bald-headedness:" "Nature having fixed man's form to her satisfaction is now putting a head on him, enlarging and fertilizing his cerebrum. By fertilizing his cerebrum is meant increasing its productiveness, and by increasing its productiveness is meant enlarging the scope and intensity of thought and ideation. And this increased mental activity requires an increased supply of blood; for not only where there is literal irritation is there 'ubi fluxus,' but wherever there is increased hæmic cellular or molecular action of any kind, or from any cause, there also is 'ubi fluxus.' The average twelve-year old boy of to-day thinks more in one day, if he does not swear more also, than grandpa of a century ago did in a week. This increased brain activity requires, as we said, an increased supply of blood, hence a greater portion of the blood-supply pumped into the carotids now goes to the brain proper than formerly, and hence a smaller portion now goes to the skull and scalp than formerly, so there is less pabulum to run to hirsute adornment than in ye olden time, and it constantly diminishes. We get brains for hair—a profitable exchange."

Died of Fumigation.—An unusual cause of death was disclosed at an inquest held a few days since. In a house where had lately been scarlet fever a young woman fumigated a room by burning sulphur in it. Entering the room the next day she was overcome by the fumes, and, although she speedily left the apartment, she died in a few hours.

MEDICAL LEGISLATION IN 1891.

By HENRY A. RILEY, A.B., LL.D.,

NEW YORK.

(Continued from p. 11.)

Delaware, Florida, Georgia, Idaho, Illinois, Indiana, Kansas.—In Delaware the legislation for the year was not specially noticeable, but the growth of the insane element of the population has been as remarkable as in other States and required the enactment of new measures.

A law was therefore passed with this preamble: "Whereas the buildings of the Delaware State Hospital for the Insane in two years' use have been found inadequate; and whereas it is fitting and proper that the institution should be a credit to the State and in every respect rendered adequate and fully equipped for the noble and humane purpose for which it is intended." An appropriation was then made of $30,000 to purchase additional grounds, erect new buildings, and repair those now in use; $20 000 was also appropriated for the annual support of the hospital Another law transferred the Insane Department of Sussex County to the State Board of Trustees for the Insane. The buildings and appurtenances were authorized to be conveyed to the State Board for $8,000. The name of the Insane Department and Hospital was directed hereafter to be the Delaware State Hospital at Fernhurst. In localities where there are no local boards of health the President of the State Board was authorized to direct any member of the Board to investigate complaints. The State Board was to have all powers and remedies now given by law to local boards. The pharmacy law was amended so as to require three years' continual practice in a retail drug store of a qualified assistant.

In Florida a law was passed in regard to the correspondence of inmates of insane asylums, which shows that the public clamor regarding alleged abuses in asylum management has had an effect upon legislators. A similar law was passed in Georgia, and will be referred to in its proper place.

The Florida statute has a preamble in which some rather strong statements are made, and is as follows: "Whereas the imprisoned inmates of insane asylums are outside the pale of justice and beyond the reach of the laws by having no means of access to the law while deprived of their post-office rights; and whereas those incapable of self defence are justly entitled to the protection of the same laws as shield all other citizens. Therefore justice demands that this link which now severs them from access to the laws should be legally established." The law then proceeds to declare that every inmate of any public or private asylum can choose one person to whom he or she can write without any interference or inspection. The correspondent can be changed every three months if desired. The superintendent of the asylum is required to furnish writing materials, postage, etc., to the extent of at least one letter a week, if the patient does not have such articles. The letters when written are to be dropped in a post-office box by the writer, accompanied by an attendant, who must see that they are directed to the correspondent. If not directed to such person they may be retained, and are subject to the disposal of the superintendent.

It is the duty of the superintendent to keep posted publicly a complete list of the correspondents of the inmates, and to request of such persons to write their names on the outside of the envelopes when replying to the patients' letters. All such letters when received are to be delivered at once to the inmates without inspection, unless they contain some substance which possibly might be used in medication. Such letters are to be opened in the presence of a competent witness and the substance delivered to the superintendent, but the letter is to be given to the person to whom it is directed.

The penalty for a violation of the law on the part of the superintendent or any official is imprisonment not to exceed sixty days, or a fine not to exceed $300, or both. The offender is ineligible for any office in any asylum in the State.

A copy of the law is required to be framed and posted in every ward of every insane asylum, both public and private.

A law was passed making it obligatory on the conductors of all railroad trains to stop at any regular or flag station in order that a physician may alight who wishes to reach a patient from such station. If the conductor shall refuse to stop a sufficient length of time to enable the physician to get off, he is guilty of a misdemeanor and may be fined for each offence from $100 to $1,000.

The law of 1887 regulating dentistry was amended, and now requires the Board of Examiners to meet at the call of three members.

It is required to grant certificates to all applicants who have obtained a diploma from a reputable dental college and who pass a satisfactory examination. A book of registry containing the names of all licensed dentists is to be kept.

For the examination and certificate a charge of $10 is made, which is to be devoted to defraying the expenses of holding meetings.

Another law requires all dentists and lawyers to pay a license tax of $10. Like several other of the States, legislation hostile to the cigarette was adopted, and it was made a misdemeanor for anyone to sell or give away any cigarettes or cigarette paper to a minor under eighteen. The penalty was imprisonment not exceeding thirty days, or a fine not exceeding $100.

The law of 1889 relating to County Boards of Health was amended, and the Secretary, who must also serve as Treasurer, was permitted to receive, in addition to the per diem allowance, compensation not to exceed $75 per month. A bond was to be taken for the proper performance of his duties.

Additional compensation, not exceeding $100 per month, can be paid the President of the Board in counties where there are seaport cities of five thousand or more inhabitants.

The rules and regulations of the State Board were to be observed by the County Boards, which were permitted to adopt other rules necessary for their localities. Violations of the law could be punished by imprisonment for six months or a fine of $1,000. The fees from disinfecting vessels, etc., and the proceeds of a one-mill tax were to be devoted to the expenses of maintaining quarantine regulations.

The legislation of Georgia during 1891 contained, as has been stated, a law securing the postal rights of patients in insane asylums, and its provisions are quite similar to those of the Florida statute in the main requirements. The Georgia law omits, however, the peculiar preamble attached to the other.

The penalty for a violation of the law is a fine of not less than $50 and not more than $500, to which can be added, at the discretion of the judge, imprisonment for a period of from ten to sixty days. The offender is also ineligible to office in any insane asylum.

A further section is added, declaring that any person who maliciously causes the imprisonment of any sane person, knowing him or her to be sane, in any public or private asylum, shall, upon conviction, be punished by a fine of from $1,000 to $5,000, and by imprisonment in the State Prison for a period not less than two years and not more than four years.

It is also required of the judges of the Superior Courts of counties containing lunatic asylums that they shall make the act a special charge to the grand juries.

Another law requires the board of trustees of the lunatic asylum to appoint a special examining board of three competent physicians which shall examine rigidly all applicants for the position of superintendent or assistant physician, as well as those persons now in office who have not been examined. Successful applicants are to hold office for two years, and the questions and an-

swers are to be preserved in the archives of the asylum.

The law of 1890, which placed a tax of $10 on all itinerant doctors, dentists, opticians, or other specialists, was amended so as not to apply to persons who had a fixed place of business and who had paid the general license tax of $10 laid upon all practitioners of law and medicine.

In the Superior Courts, in trials for seduction or divorce or other cases, where the evidence is vulgar or obscene and tends to debauch the morals of the young, the presiding judge shall have the right, of his own motion, to try the case after clearing the court room of all or any portion of the audience.

A general law was passed making it unlawful to sell or offer for sale any spirituous, alcoholic, vinous, or malt liquors within three miles of any church or public or private school-house. This would seem to be virtual prohibition, but an exception was made in the case of incorporated cities and towns, and also in the case of regular practising physicians, who were allowed to dispense alcoholic stimulants for medical uses in their practice.

Another law made it unlawful for anyone to carry intoxicating liquor to church, but an exception was made in the case of physicians, who could carry what they deemed necessary in their regular practice.

Cotton-seed-meal was required to be analyzed by the State chemist before sale, and must be marked as second class unless it contained at least seven and one-half per cent. of ammonia.

An appropriation of $15,000 was made for a steam laundry and water-works at the Georgia Institution for the Deaf and Dumb.

In Idaho most of the legislation shows signs of the new conditions prevailing in a partially developed State. It is declared to be the duty of the Board of Education to ascertain the number of deaf, dumb, and blind children of school age and sound body in the State, and to provide as soon as possible for their education if their parents were not able to. An appropriation of $3,000 was made for this purpose. An appropriation of $35,000 was also made for purchasing grounds, erecting buildings, and making improvements at the Idaho Insane Asylum.

All practising physicians were declared to be exempt from military duty.

A law was passed providing that no punishment should be inflicted on a convict except solitary confinement on bread and water, or wearing a ball and chain attached to one leg.

Registered druggists could sell without a license spirituous and vinous liquors on the written prescription of a regular practising physician who certifies that in his opinion the health of the party to whom the liquor is sold would be promoted by its use.

Fruit-trees, even in that new country, would seem to be affected by the codlin moth and other injurious insects, for horticultural commissioners were authorized to be appointed with full powers for investigating and abating as public nuisances the orchards or salesrooms where the insects were found.

In Illinois the State Board of Health was directed to choose its secretary from its members, and the salary of the office was fixed at $3,000

Ten thousand dollars were appropriated for a contingent fund, to be used with the consent and concurrence of the Governor, in case of the outbreak or threatened outbreak of any epidemic or malignant disease, such as Asiatic cholera, small-pox, yellow fever, or to defray the expenses of preventing the introduction of any such diseases or their spread

Cities of one hundred thousand inhabitants or over were authorized to establish public hospitals, which should be non-sectarian, and were to be supported by the levy of a two-mill tax. The board of directors should consist of three members, one of whom might be a woman. The hospitals were to be for the benefit of all the inhabitants, but everyone except paupers must pay reasonable compensation for nursing, care, medical attendance, etc. It was provided that all physicians who are recognized as legal practitioners by the State Board of Health shall have equal privileges in treating patients.

The dislike for the English sparrow seems to have culminated in Illinois, for a statute was passed which gave a bounty of two cents for every sparrow killed during December, January, and February. The bodies or heads must be presented to the County Clerk in lots of ten or more, and he must then draw a warrant on the County Treasurer.

It is required of the Director of the State Laboratory of Natural History that he prepare a bulletin of information for use of the County Clerks, so as to enable them to distinguish the heads of English sparrows from those of other birds. If a person presents the heads of birds other than sparrows, claiming a bounty, he is to be fined $5 for each head.

A law was passed establishing the Illinois State Reformatory at Pontiac, and the new method of reforming criminals by the parole system was directed to be carried into operation. If the offender is between the ages of ten and twenty-five, has not been previously convicted, and the crime is not a capital one, the sentence of commitment shall be a general one, and the duration is not to be fixed. The time shall not, however, be longer than the maximum now established by law, and may be shortened by the managers of the Reformatory.

A physician shall examine each prisoner and enter in a register the name, nativity, race, weight, stature, and family history; also a statement of the condition of the heart, lungs, and other leading organs, the rate of pulse and respiration, the measure of the chest and abdomen, and any existing disease or deformity A register is also to be kept by the Superintendent of all facts about the age, nativity, parentage, education, occupation, early social influences and tendencies which may seem to indicate the constitutional or acquired deficiencies of the prisoner, and the best possible plan of treatment. He shall also keep minutes of the improvement or deterioration of character of all prisoners.

The Board of Managers have the power to release prisoners on parole, but they are under legal custody and can be taken back. No prisoner is to be released unless arrangements have been made for honorable and useful employment for at least six months at some suitable occupation.

The Superintendent must keep in communication with a paroled prisoner, and if he gives evidence after six months' employment that he will not be guilty of further violations of the law, a report shall be made to the Managers, who may make an entry of discharge, and send the record to the judge imposing the sentence. Such judge will thereupon enter a formal order of discharge.

If a prisoner violates his parole he shall be treated as an escaped prisoner, and upon arrest shall serve out the maximum time.

The cutting of the solid part of a horse's tail, a brutal act called "docking," is forbidden unless it is proven to have been a benefit to the horse. The punishment is imprisonment not to exceed one year, or a fine of from $25 to $200.

An appropriation was made of $163,000 for the erection and furnishing of new buildings to accommodate three hundred additional patients at the Eastern Hospital for the Insane at Kankakee, and of $71,000 for repairs and other new buildings.

An appropriation of $35,000 was made to purchase farm lands and make improvements at the Illinois Asylum for Feeble-minded Children at Lincoln.

The Illinois State Penitentiary at Joliet received $100,000 to keep the convicts employed and for the purchase of tools, machinery, raw materials, etc.

In Indiana a law was passed establishing a State Board of Health, consisting of five members, with a Secretary, who must be a physician and shall be styled the Health

Officer of the State. It is the duty of the Secretary to collect information regarding vital statistics, diseases, hygiene, etc., and to present the same in an annual report. Information shall also be disseminated among the people on these subjects in such manner as the Board may direct. The Board shall have general superintendence of the health and life of the citizens of the State. They shall study the vital statistics and endeavor to make intelligent and professional use of the collected records of death and sickness among the people. They shall make sanitary investigations and inquiries respecting the causes of disease, and especially of epidemics, the causes of mortality, the effect of employments, habits, circumstances, etc., on the health of the people.

An annual report, with suggestions about legislation, is to be made by the Board. The Boards of Commissioners of each county are made local Boards of Health, and it is the duty of such Boards to prevent the spread of contagious diseases, to abate nuisances, etc., and to carry out the regulations of the State Board. A refusal to carry out these regulations is made a misdemeanor and punishable by a fine of $100; for a second offence imprisonment for ninety days may be added. The salary of the Secretary of the State Board is not to exceed $1,200, and $5,000 is appropriated for all expenses.

A law was passed for the protection of birds, nests, and eggs, and it was made unlawful to kill other than game birds, under a penalty of thirty days' imprisonment and $50 fine. The Executive Board of the Indiana Academy of Sciences was authorized, however, to grant permits to properly accredited persons for the collection of birds' nests or eggs for strictly scientific purposes. Such persons must present testimonials from at least two well-known scientific men and also give a bond for $200.

A general charter was provided for cities of over one hundred thousand inhabitants, which granted ample powers for securing public comfort and health. A Department of Health and Charities was established, with three Commissioners, all practising physicians, and to be appointed by the Mayor. The department was to have charge of all health matters, hospitals, etc., and was to elect one of the Commissioners to be Registrar of Vital Statistics, who should attend to the proper registry of all births, marriages, and deaths. Special sanitary officers were to be appointed to inspect live-stock, meat, food products, etc., to examine plumbing and to attend to the proper fumigation of infected houses, etc.

The Medical Practice law of 1885 required all practitioners of medicine to procure licenses from the clerks of the Circuit Court of the counties where they practised. This law was amended in 1891 so that a license procured in one county enabled the holder to practise in any other county.

An important law was passed providing careful safeguards for the working of coal mines, so that the lives and health of the miners would be better protected, and another law required mercantile establishments, manufactories, etc., to provide seats for female employees when not actively engaged in their duties.

The Board of Trustees of the Eastern Indiana Hospital for the Insane was abolished and a new Board of three members provided for, to be elected by the General Assembly. The duties of the new Board were declared to be the same as required of the Board of Trustees for the Additional Hospital for the Insane. Appropriations were made of $45,000 for the construction, equipment, and furnishing of the Southern Indiana Hospital for the Insane; of $10,000 for the Indiana Institution for the Education of the Blind, to provide new buildings and general improvements; of $11,000 for a building for the Industrial Department of the Indiana School for the the Feeble-minded Youth, and of $17,500 for general improvements at the Indiana Institution for the Education of the Deaf and Dumb.

In Kansas the legislation did not contain any laws directly affecting physicians, but a statute was passed for the regulation of dentistry. It provided that any person desiring to practise dentistry, and not holding a diploma from any dental school or college or university department, shall be entitled to be examined by the Board of Examiners provided by the law of 1885.

The Board shall fairly and impartially inquire into the qualifications of said person with reference to his knowledge of practical dentistry, and if a majority of the Board shall certify that in their opinion he has a sufficient knowledge of practical dentistry to entitle him to engage or continue in practice, a certificate shall be issued. The applicant must pay $20 for the examination.

A curious bit of legislation is found in a law appropriating $3,500 for establishing, maintaining, and conducting an experiment station at the State University at Lawrence to propagate the contagion or infection that is supposed to be destructive to chinch bugs.

The Prohibitory Liquor law was amended so as to allow wholesale druggists and dealers in photographic supplies to sell to registered pharmacists or photographers any amount of alcohol over one quart on a written certificate that the buyer does not intend it for a beverage nor to give away.

Any person making a false certificate is guilty of a misdemeanor, and can be fined from $100 to $400, and be imprisoned from thirty to ninety days.

The manufacture of vinegar, except from apple cider, is forbidden, and also any adulteration by drugs or acids, under a penalty of a fine varying from $50 to $100.

A law regulating the management of the State Penitentiary provides that there shall be no corporal punishment of convicts, no painful or unusual kind of punishments, such as binding the limbs, or keeping the person in a painful posture. Punishment is to be restricted to the ball and chain, but not so as to torture the person or limbs, and to close and solitary confinement, with such deprivation of light and limitation of kind and quality of food as may in the exercise of a sound discretion produce distress without hazarding the health of the offender.

If a convict becomes insane the prison physician shall summon the two nearest resident physicians and investigate the case. If deemed insane, the convict may be confined in the insane ward, or the Board of Directors may remove him to the Insane Asylum. If he recovers before the expiration of his sentence, he may be sent back to the prison.

A law was passed prohibiting the editing, publication, or circulation of any newspaper, magazine, etc., devoted largely to the publication of scandals, lechery, intrigues, etc., and the person offending is guilty of a felony, and may be imprisoned in the penitentiary for a period of from two to five years.

The importance of the cattle industry is significantly shown by the penalty imposed for driving or turning into any highway cattle capable of communicating Texas, splenetic, or Spanish fever. The offence was made a misdemeanor, and punished by a fine of not less than $500 and not more than $2,000, or imprisonment in the county jail for a period of from thirty days to one year.

In addition, the person was liable civilly for all damages suffered.

An appropriation was made of $9,000 for the erection of an industrial building at the Institution for the Education of the Deaf and Dumb at Olathe.

(To be continued.)

Second-Hand Teeth.—A reporter of one of the daily papers has discovered a dealer in second-hand sets of false teeth. He buys them at pawnbrokers' sales for from ten to thirty cents, and sells them for about three dollars, so there is a fair margin of profit in the business. But it is not pleasant to contemplate the abject poverty that has driven the original possessors of these artificial teeth to pawn them for a few cents.

A FEW BRIEF REFLECTIONS UPON THE ANCIENT DOGMA OF MATERNAL IMAGINATION OR IMPRESSION AS A FACTOR OR A DISTURBING ELEMENT IN THE PRODUCTION OF NUMEROUS AND VARIOUS ABNORMALITIES OF THE EMBRYO OR FŒTUS IN UTERO.

By WILLIAM BODENHAMER, M.D., LL.D.,

NEW YORK.

From the very numerous and remarkable examples of the influence of maternal impression upon the embryo or fœtus in utero which are constantly being reported in the medical journals by physicians, the writer also feels moved to make a few brief remarks upon this recondite subject for what they may be worth. He could also report several remarkable instances illustrative of the subject which came under his own observation during a practice of many years, but deems it unnecessary, or a work of supererogation, inasmuch as the case, in his opinion, is quite sufficiently established without calling any more witnesses to the stand.

The ancient dogma of the influence of the maternal imagination or impression upon the embryo or fœtus in utero is a theory or sentiment which has grown gray with the growth of ages, is crystallized by time, and confirmed by innumerable and varied examples which are as indisputable as they are inexplicable. Indeed, the records are rich in instances exemplifying this very dogma or opinion. Many of the most distinguished ancients held it; for instance. Hippocrates, Galen, Celsus, and other ancients generally, paid much attention to the various fœtal vices of conformation, which they attributed to the influence of the mother's imagination. Indeed, some of the writers of all ages were of opinion or belief that the embryo and the fœtus were susceptible in some manner of psychical, mental, and physical impressions or influence. Some writers, however, have always been found who attribute these fœtal defects to other causes or sources than that of the influence of maternal impression. Aristotle calls them "errors of creation." Pliny mentions them in these words, "Ludibria sibi nobis miracula ingeniosa fecit natura." Some writers allude to them as blind and chance productions, and inexplicable natural wonders, bizarre and sportive formations; while others again attribute them to the influence of evil spirits or witches, as some of our good forefathers supposed. At the present day a large number regard these fœtal abnormalities, or deviations from the normal standard, as merely remarkable coincidences. Mr. John Wilson considers nævi, or mother's marks, which have been said to resemble strawberries, currants, etc., to be nothing more than a morbid alteration or hypertrophy of the vascular tissue of the dermis. What Mr. Wilson says is doubtless true, but the question here is not what their pathology is, but what is their cause or origin?

The writer takes it for granted that the dogma of the maternal imagination or impression as a factor in the production of various preternatural changes, defects, and some diseases of the embryo and the fœtus in utero, is established beyond all doubt, from the numerous and overwhelming facts which have accumulated and still continue daily to accumulate. Indeed this theory finds its prototype in the Bible, and thus comes down to us in an unbroken chain through these many centuries; and is even now held and maintained by a large majority of the scientists of the age, who admit that the mental condition of the mother can be phrenographed, as it were, in the physical development of her offspring. If this is true, and there is no evidence to the contrary, no valid reason can be given why the influence of maternal emotion should not be classed among the disturbing causes of fœtal development and disease. Upon this subject the writer made the following remarks in his treatise on the "Congenital Malformations of the Rectum and Anus," published in 1860, p. 41: "Is it at all possible for the maternal imagination to be so wrought upon as to cause a partial or a total arrest of development, or an excess of development, in any portion of the fœtus? Will anyone deny that a sudden fright of the mother might not be sufficient to destroy the life of the fœtus; or refuse to admit that prolonged and vivid impressions of the mother, of whatever character, might not give rise to disease in the fœtus, and such disease ultimate in death or in the malformation of some organ?"

But whether this theory be true or false, it stands today intact, never having as yet, so far as the knowledge of the writer extends, been successfully disproved or refuted by any fair, logical, and satisfactory argument or rational explication.

Such phenomena doubtless depend upon fixed laws, of which, however, we are as yet ignorant, and only know of their existence by witnessing their numerous and strange effects.

The writer would here remark, however, that the fœtus in utero is liable to many malformations, as well as many diseases, which are entirely independent and beyond the influence of maternal imagination or impression.

M. Mauriceau, two centuries ago, held and published opinions relative to the causes and sources of the various abnormalities and diseases of the fœtus in utero which differ but little from those of the present day. Fredericus also, in 1658, published a learned and interesting work in Latin pertaining to the same subject. These two able authors give much curious and valuable information, the result evidently of extensive observation and research.

The subject of maternal imagination or impression has recently been very ably and learnedly discussed by the following distinguished medical gentlemen of our own country: Dr. B. W. Palmer, of Detroit, Mich., editor of the *Medical Age*; Dr. W. R. Lowman, of Orangeburg, S. C.; and Drs. E. C. Spitzka and E. C. Seguin, of New York City.

There are numerous well-authenticated cases on record of the evil or deadly effects of violent passion, profound grief, sudden fright or shock, alarm or fear, acting upon the *enceinte* mother. Some cases are related in which pregnant women after violent fits of passion have been delivered of dead children. May not some of the worst of such cases receive an explanation in the extreme agitation of the maternal system and the temporary suspension of the uterine functions to which such powerful and often-repeated agitations give rise.

There are some authors who, believing in the utero-placental nervous connection and the immediate influence of the maternal impressions upon the fœtus, imagine that too great an amount of nervous power may be thrown into its feeble organism, and that it destroys life in the same manner as that produced by an electric shock. It is supposed by them that electricity itself is a cause of the death of the fœtus, either by passing along the utero-placental nerves or being conducted to it through the liquor amnii.

M. Mauriceau records a number of cases of fœtal abortions and death as having resulted from "une grande peur ou chagrin." The French surgeon, M. Baron Percy, gives a very graphic illustration of the dreadful effects of maternal emotion and impression upon the fœtus in utero in his vivid description of the siege of Landau, which occurred in 1793. The Baron says: "In addition to a violent cannonading which kept the women in a constant state of alarm, the arsenal blew up with such a terrific explosion as few could bear with unshaken nerves. Out of ninety-two infants born in that district, within a few months after the occurrence, sixteen died at the instant of birth; thirty-three lingered from eight to ten months; eight became idiotic and died before the age of five years, and two came into the world with numerous fractures of the limbs."

M. Pinel observed the large number of insane, idiotic, and malformed children born during and shortly after the

intense excitement of the French Revolution. Our own countryman, the late eminent and highly distinguished Dr. Rush, also observed the large number of malformed and idiotic children born during the American revolutionary period. Dr. Andrew Combe, in his treatise on insanity, has also recorded some curious facts illustrative of this same subject, and he also alludes to the well-known circumstance of what Pinel and Rush had observed in their respective countries during the revolutionary period in each.

Dr. Lowman, speaking of profound grief, mental or physical shocks acting upon the mother and producing defects, mentally and physically, in the child, refers to instances which have occurred within recent dates. He says Dr. Spitzka gives the statistics of Legrand du Saulle, in reference to the *ouvriers* of Paris, of the defective children born in 1871, as "enfants du siége." The French are known to be exceedingly impressionable and emotional. Of ninety-two children born in Paris during the siege, sixty-four had mental or physical anomalies, and the remaining twenty-eight were weaklings, twenty-one imbecile or idiotic, and eight showed moral obliquity or emotional insanity. The financial crises in Berlin, in 1875 and 1880, were followed by an increased number of idiots born.

Now, it may be asked, are the foregoing phenomena capable of being explained upon physiological and natural principles? The defective intellects especially seem to be almost moved beyond our calculations. But may they not rather be owing to the frantic passions and bewildered intellects of both the parents themselves, at the time of conception, than to any subsequent influence of the mother's imagination; and may not the damaging effects of such a continued state of mind and body, on the health of the mother, be amply sufficient to account for the absence of mental and bodily vigor in the offspring?

A CASE OF EXTRA-UTERINE PREGNANCY.

By FORBES R. McCREERY, M.D.,

New York.

So much has been said and written of late on the subject of extra-uterine pregnancy that I think the following case may be of interest:

Mrs. W——, aged twenty-eight, married, United States, 0-para. Mrs. W—— has always suffered pain from dysmenorrhœa. This has grown less severe of late years. Periods have usually been delayed from three or four days to a week. They have lasted three or four days. She was married first in 1882. Her husband died six years later. Three years ago she married again.

About four years ago she had an "abscess" near the rectum and another in the right groin. The latter opened into the vagina. At that time the menses ceased and did not recur for thirteen months.

In May, 1890, the menses ceased again. Nursing nausea began in June. From July on she suffered greatly from pain in the right iliac region and in the back, bearing down, frequent chilly sensations, alternating with feverishness, vomiting, and loss of flesh and strength. In six months her weight fell off from one hundred and seventy-five to one hundred pounds. An abscess was diagnosticated, and on December 2, 1890, exploratory laparotomy was performed. Apparently the cause of the trouble was not found. After the operation her chills and fever left her, and she gained somewhat in flesh and strength, but still remained far from well. In April she began to pass fœtal bones per anum. This continued during May. From that time on no bones were passed, but she suffered greatly from rectal tenesmus, painful defecation, and frequent discharges of pus from the rectum.

I first saw the patient on August 17, 1891. At that time she was suffering much from the symptoms just detailed. She had had a slight chill the week before. She gave also the history and physical signs of incipient chronic tuberculosis. On vaginal examination a large, hard, tender mass was found in Douglas's cul-de-sac. On passing the finger into the rectum the same mass was felt, and about two and one-half inches from the anus, a small opening into the bowel was found. Through this projected a bone with rough, serrated edge.

On August 20th, with the assistance of Dr. Jeffry, ether was given, and the bones removed. Considerable difficulty was found in so doing. I attempted at first to use a rectal speculum, and seize the bones with forceps. This, however, proved impracticable, and I was forced in the end to pass my fingers into the abscess cavity, and scrape out the bones in that way. Instruments were of little use, and most of the work was done with the fingers. The cavity was irrigated with bichloride solution. For several days after the operation there was slight fever, with some local pain and tenderness. This subsided under appropriate treatment. On the 29th I found the same mass in the cul-de-sac, but it was much reduced in size, and only slightly tender. The rectal tenesmus and purulent discharge had entirely ceased. It seemed to me that there was nothing left beyond the remains of the sac in which the fœtus had lain, and the surrounding adhesions.

The bones removed were perfectly free from soft parts. The largest was one of the frontal bones. This was the one I had felt projecting into the rectum. There were two or three ribs, one ulna, and about six or eight of the smaller bones. They are at present in the museum of the New York Hospital.

Since August I have seen Mrs. W—— a number of times, but have had no opportunity to examine her. She has had no return of the rectal symptoms. She suffers a good deal at times from pain in the lower portion

of the abdomen. She has also at times a dry cough, and there have been uncertain signs of infiltration at both apesis. These, however, seemed to me to have advanced little, if at all, since I first saw her. Her general condition is much improved.

FRACTURE OF THE PENIS.

By GEORGE HERBERT WILLIAMS, M.D., M.R.C.S. Eng., L.R.C.P. Edin.,

NEW YORK.

On February 1st, about midnight, I was called to see A. B——, a Hebrew, about thirty years of age. I found him greatly agitated, and sitting up in bed holding his penis. As soon as he saw me he called out several times in great distress, "Oh, doctor, I have broken my penis!" On examination I found blood escaping from the urethra, the sheets and patient's hands soiled with blood, and the penis arched toward the left with a distinct sulcus midway between the symphysis pubes and the glans, the whole organ very much engorged, more especially the right corpus cavernosum, and the skin of a darkish blue color. The patient gave the history of an old stricture, which he had been treating with Ag. No. 3 bougies, under medical advice.

History of Accident.—About half an hour before, on getting warm in bed, the organ being in an extreme condition of engorgement, he had forcibly tried to turn it down under the left thigh.

Treatment.—A number of English gum elastic catheters was passed without much difficulty into the bladder, and a small quantity of normal urine drawn off. On withdrawing the instrument a small clot was entangled in its eye. Fearing sloughing, which must have inevitably taken place, fourteen small incisions were made, mostly on the right side, and toward the distal end of the organ. Considerable blood and serum were allowed to escape, the part was freely dusted with iodoform, and enveloped in a linseed poultice, the glans being left uncovered. After the incisions patient expressed himself much relieved, but the part was still very swollen, blackish, and bent over to the left; the privates were raised on a soft pillow. The poultices were renewed every two hours during the night. At my morning visit the parts looked better, and were not quite so much swollen.

Much the same treatment was continued for six or seven days, the poultices every three hours, and a soft rubber catheter left with the patient. All the incisions at the end of a week were healed, except one just behind the glans, on the right side, and the penis had almost recovered its normal size and color. On the eighth day the poultices were discontinued, and a dressing of iodoform 3 j. in lanoline ℥ j. used, being spread on lint and changed twice a day.

On the eve of the ninth day patient had difficulty in passing the catheter, and found the urine ran along its side and escaped from the unclosed incision on the right side; with considerable force, however, this was avoided in the future by using a full-sized rubber catheter, and emptying the bladder three times in the day. The patient left his bed on the fifteenth day, the iodoform ointment being still used. When I saw him last on February 19th, the wounds were all healed and the penis looked normal, the catheter being discontinued.

The case has seemed to me so unique in its details that I have ventured to record it, having never in a large hospital experience seen anything quite like it.

The fact of the patient being circumcised was, of course, in his favor as regards the final result.

It would seem that the hemorrhage from the urethra following the accident, and subsequent escape of urine from the wound mentioned, and the peculiar bending of the organ, pointed to the fact that the penis had practically undergone a green-stick fracture, with a rent of the urethra on the side of the convexity; in fact it was possible at the last examination to trace a tract of adhesive inflammation from below upward, and along this the urine must have made its way.

173 West Eighty-first Street, March 3, 1892.

PARALYSIS AND CONVULSIONS CURED BY TREPHINING.

By F. J. ADAMS, M.D.,

GREAT FALLS, MONT.

Some time since I was very much impressed by an article by Dr. J. W. White, of Philadelphia, on "The Supposed Curative Effects of Operations *per se*;" and thinking, perhaps, that many of your readers are as interested in the subject, I send you a report of an interesting case of paralysis and convulsions that were entirely cured by an operation, though no abnormal condition was discovered.

James W——, Irish, aged twenty nine; cowboy by occupation. While engaged in a saloon row on September 21, 1891, was shot in the head. The ball, from a 44-calibre revolver, penetrated the scalp and fractured the skull one-half an inch anterior to and one inch above the right parietal eminence. The ball did not penetrate the skull, but gouged out a piece of bone about the size of a silver ten-cent piece, causing a hernia cerebri. The protruding portion of brain was removed and the edges of the scalp wound trimmed and drawn together with sutures, and an antiseptic dressing applied. There was complete hemiplegia of the left side and paralysis of the right leg, difficulty in deglutition, and also impaired memory and hesitancy in speech. His temperature the day following the accident was 102° F.; his pulse, 100. The pulse and temperature remained about the same for five weeks, at the expiration of that time there was no fever. The wound had united and was perfectly closed, but the paralysis remained the same. I would say there was loss of sensation on the left side also. On October 29, 1891, he commenced having convulsions on the left side, which were as frequent as every half-hour and lasted from two to five minutes. The convulsions would always begin in the muscles of the face and gradually extend to the muscles of the left extremity. During the convulsions there would be great dyspnœa. On November 4th I saw the patient again, in consultation, and advised trephining. Accordingly on November 12th the patient was etherized, the scalp shaved and prepared antiseptically. A horse-shoe incision was made in the scalp to include the periosteum. The flap was reflected, the trephine applied, and a button of bone about one inch in diameter removed and immediately placed in a hot bichloride solution, 1 to 4,000. Nothing abnormal was discovered except a very trifling depression of a small portion of the frontal bone, certainly not enough to cause the symptoms noted. The depressed portion of bone was raised, and the button of bone that had been removed by the trephine was broken in small bits and replaced in the wound. The man reacted nicely; the convulsions disappeared on the second day following the operation, and both the motor and sensory paralysis at the same time began to improve. At present he has good use of both legs, and is able to walk without the aid of a cane; the only complaint is the occasional giving away of the left knee. He has also excellent use of his left arm. He has no hesitancy in speech and his memory is entirely restored; in fact, the man has made a most remarkable recovery. The button of bone united firmly, and the only evidence of an operation is a linear cicatrix about one line in width and the shape of the original incision.

She Would be Beautiful.—A woman was arrested not long ago in London for drunkenness, who was found afterward to be suffering from the toxic effects of atropine, which she had instilled into the eyes to dilate the pupils and give the organs a brilliant appearance.

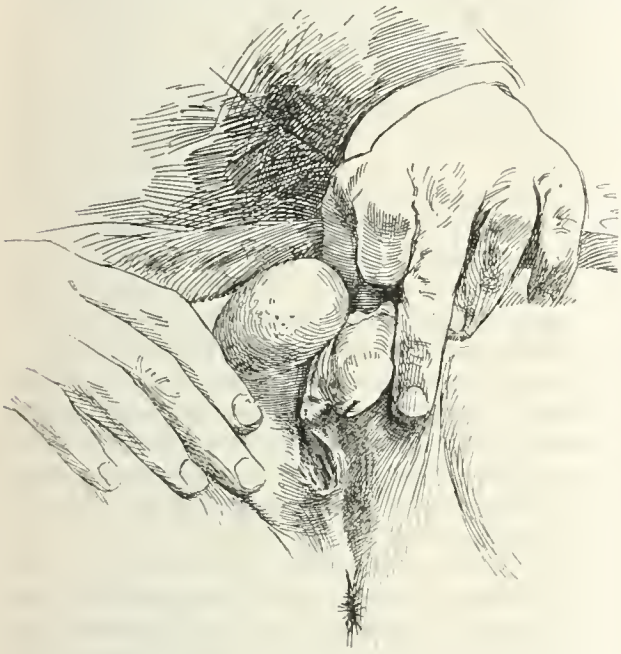
HERMAPHRODITISM, SPURIOUS.

By H. D. BISHOP, M.D.,

LECTURER ON GENITO-URINARY DISEASES, CLEVELAND HOSPITAL COLLEGE, CLEVELAND, O.

THE following case of spurious hermophroditism is one of interest from the fact that the deformity is such a marked one of hypospadias.

The patient has the following interesting history. Up to his seventeenth year, five years ago, he was thought to be a girl. His parents were aware of some deformity, but had never consulted a physician in regard to it. At that time a physician was called to attend him for some slight ailment. During his attendance he discovered the true sex of his patient. From that date he assumed man's attire. His general appearance is masculine; beard light, breasts perfectly normal in size. The external genital organs are those of a male, but partially correspond in appearance to both male and female, as is shown in the accompanying illustration. Lying di-



rectly upon the pubis on the right side is a fully developed testis ensheathed in a fold of loose tissue which passes down forming a close resemblance to the labia majora. On the left, in a corresponding position, is an imperfectly developed testis ensheathed as on the right and a fold corresponding to the left labia majora.

The penis occupies a normal position. The glans and prepuce are developed and, in the state of erection, the penis is perhaps three inches in length. The meatus is normal and there is the beginning of the urethral canal. Immediately below the symphysis is a narrow strip of mucous membrane which extends downward a distance of two and one-half inches, terminating in an opening corresponding to the deep portion of the urethra. There is no evidence or any organ distinctively that of a female.

At the age of fourteen he had an illness which his mother ignorantly interpreted as the beginning of his menstrual function. For the past six years he has practiced masturbation. He accomplishes this by manipulating the above-mentioned strip of mucous membrane below the symphysis. The act is followed by an orgasm, with a discharge of prostatic fluid. No traces of spermatozoa are present on a microscopical examination.

The Onus Probandi of Medicine.—A writer in an esteemed contemporary refers to tuberculosis as one of a "class of diseases which have so long been the *onus probandi* of medicine." We should smile.

Progress of Medical Science.

Hairs in the Stomach.—Quoting from a German medical journal, the *Mercredi Médical*, February 10, 1892, cites a case recorded by Bollinger, in which an autopsy, performed to discover what kind of malignant growth had caused death, revealed the presence of a compact mass of hair, weighing 900 grammes, in the stomach and intestine. This mass formed an exact cast of this portion of the digestive tract. The girl, it was afterward discovered, had for over ten years been in the habit of pulling out her hair and swallowing it. There are six similar cases in literature, all in young girls, not diagnosticated during life. In one instance, the seventh on record, an error in diagnosis led to an operation that resulted in saving the patient. Bollinger looks upon the habit as a species of pica, such as is observed among the insane, the hysterical, the chlorotic, and pregnant women.

Hiccough Cured by Compression of the Phrenic Nerve.—In *Mercredi Médical*, February 10, 1892, there is an account of complete and permanent cure of persistent hiccough by a simple and convenient method. The patient, a child twelve years old, suffered from hiccough every half minute; the trouble resisted all treatment, made sleep next to impossible, and induced such impairment of nutrition that the child's life seemed in danger. Leloir, the last physician consulted, hit upon the lucky expedient of forcibly compressing, by means of the finger, the left phrenic nerve between the two sterno-clavicular attachments of the sterno mastoid muscle. The pressure being maintained uninterruptedly for three minutes, in spite of the somewhat painful nature of the proceeding, the hiccough ceased, never to return. Leloir states that he has tried this remedy many times since with equally favorable results.

Hypnotic Treatment.—Dr. Sperling offers the following conclusions regarding the employment of hypnotism: 1. The methodical employment of hypnotism as a therapeutic measure is plainly justifiable. 2. The physician alone should make use of this means of cure. 3. Physicians should not abandon this method to empirics nor even to inexperienced hands. 4. Public exhibitions of hypnotism should be forbidden, so as not to vulgarize the method and bring about undesirable consequences. 5. In certain particular cases the therapeutic result depends (*a*) on the precision of the indication, (*b*) on the method employed, (*c*) on the personal influence of the physician upon his patient. 6. The variations inherent to each separate individual prevents us from establishing any general rules for the employment of therapeutic hypnotism. 7. The author has found no inconveniences from the method.—*Journal de Médecine de Paris*, October 18, 1891.

A Cohnheimoma.

WHO can diagnose lipoma
From malignant carcinoma?
Or a simple osteoma
From deep-seated angeioma?
An innocent chondroma
May be thought a fierce sarcoma;
Strong and muscular myoma
May reinforce fibroma,
Till the fidgety neuroma
Nerves himself to ask myxoma
Why in thunder old lymphoma
Disowned lymphangeioma?
And if warty papilloma
Simulated adenoma,
Would the patient carry home a
Wound and die in coma?

F. C. BURRINGTON.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place.

New York, March 19, 1892.

A DEFENSE OF THE HABITUAL USE OF OPIUM.

ONE of the worst of the many instances of oppression of a weak nation by a strong one was the forcing of opium upon China, and very few are the voices that have been raised in extenuation of the crime. Among the most eloquent of these apologists is Surgeon-General Sir William Moore, who seems to think that China owes a debt of gratitude to England for not being permitted to restrict the use of opium. In an article in the *Provincial Medical Journal* of February 1, 1892, he supplements his former writings on this subject by an elaborate argument, in which he attempts to show that opium addiction is, to the Chinese at least, a blessing rather than a curse.

So far, he intimates, from the Chinese becoming deteriorated by their indulgence in opium their condition as a nation has been benefited by it. Formerly they were a very drunken people, but now they are temperate in the use of alcohol, and have in consequence become an essentially aggressive people, and "have proved themselves to be the strongest, most industrious and enduring, as well as the most thrifty and provident of all nations." The emaciation, sallow complexion, muscular tremor, and mental weakness, said to be characteristic of the opium consumer, are, he contends, the result only of the excessive use of the drug, the majority of those habitually taking opium being "hale, hearty, and powerful, and with intellects undulled." Another assertion which he characterizes as incorrect is that the opium habit once contracted cannot be given up, but he supports his view with little more than a simple denial, citing only an anonymous letter to the *Times*, in which the writer says that the habit is not in any case irremediable, and an instance mentioned by Sirr of a confirmed smoker who abandoned the use of the drug. An assertion that the confirmed inebriate can always give up the use of alcohol if he so desire may be supported by much stronger testimony than this. Very possibly a man who has indulged moderately and for a short time in opium-smoking may give it up if he desires, just as one who habitually drinks alcoholic liquors may abandon the habit. But if the general consensus of medical men and of missionaries to the East, whose authority is based upon long observation, has any weight, it must be admitted that the opium disease follows upon habitual indulgence much more certainly than does the alcohol disease. Indeed, it is the almost universal testimony of credible witnesses that the habitual use of opium enslaves its victims and that the habit is, Sir William Moore's anonymous authority to the contrary, in most cases irremediable.

The author devotes a few lines to a comparison between opium and alcohol, in which the advantage is by no means on the side of alcohol. "It has been asserted," he says, "that the use of opium is more deleterious than the use of alcohol. This may be considered under two aspects, moral and physical. As regards the moral effect it may be conceded that the immoderate use of both alcohol and opium are degrading; but the moderate use of opium is certainly not more degrading than the moderate use of spirits—*i.e.*, it is not degrading at all! Opium users are not 'run in' as drunk and disorderly; they do not engage in brawls; they do not 'jump on their wives;' and they never display the different stages of inebriety. There are thousands of men in Eastern towns, Bombay for instance, who in almost all conceivable capacities are good masters and good servants and yet use opium. The fact is, spirit disorders the mental faculties, opium brightens them; spirit robs a man of his self-possession, opium sustains it. There is no reason why opium-smoking necessarily degrades a person more than does the smoking of tobacco. As regards the physical effects of opium no special disease has been traced to it, excepting, perhaps, constipation at first, and after immoderate use weakness, depression, and a semi-hysterical condition, often terminating in diarrhœa. The influence of opium-smoking is entirely on the nervous system and is not permanent. Alcohol causes well-known permanent organic changes. It affects the liver, the heart, the kidneys, and it may cause paralysis and lunacy. It also often causes delirium tremens. None of these results occur from the use of opium."

This is manifestly an unfair comparison, for it is between the effects of opium taken in moderation and those of the immoderate use of alcohol. An occasional glass of wine or beer, or even of rum or whiskey, does not disorder the mental faculties or rob a man of his self possession, neither does it cause cirrhosis of the liver, paralysis and lunacy, or delirium tremens. On the other hand, opium-smoking in excess does not brighten the mental faculties or sustain a man's self possession, but just the contrary.

In comparing the effects of opium-smoking and opium-eating, the author is more fair. It is a mistake, he holds, to say that opium-smoking is more deleterious than opium-eating, and cites a number of authorities to the effect that the former is much less injurious, even when indulged in to excess, than the latter. The opium used for smoking, called "chandul," is "boiled, filtered, and otherwise manipulated, by which a considerable portion of the narcotin is removed. The only matters remaining capable of producing physiological effects are morphia, codeia, and narceia. When chandul is used it is not smoked like tobacco. The bowl of the pipe is so held that the flame of a lamp catches the chandul, and the effect of the ensuing combustion is destruction of much of the remaining active principles of the opium. A portion of the remaining morphia is sublimed and deposited in the pipe before it reaches the mouth of the smoker. Sir George Birdwood concludes that nothing passes from the deflagrating chan-

dul pill into the lungs but the volatile resinous constituents of opium."

Nevertheless, opium-smoking is physically injurious and mentally and morally degrading. The assertion to the contrary may be made with comparative safety in England, where opium-smoking is little or not at all indulged in, but it will hardly be accepted in this country where the opportunity for studying the results of the vice is unfortunately so near at hand. There are not "a million of smokers" in the United States, as Sir William Moore intimates, but there are a great many, and for their moral and physical degradation England is in a measure indirectly responsible, since she has done her best to increase the prevalence of the vice among the Chinese, who are now propagating it in this country.

A NEW TREATMENT FOR ACUTE GONORRHŒA.

Dr. C. E. Cotes, in the *British Medical Journal*, describes a new treatment for gonorrhœa which he tells us cures the disease within twelve days. The technique of the method is as follows:

The patient is first made to micturate, and thus remove the discharge from the urethra, as far as possible. The endoscopic tube, warmed and oiled, is then passed into the urethra, the patient lying on a couch. As a rule the passage of the instrument gives rise to but slight pain, but occasionally, in sensitive patients, or where inflammation is very acute, a ten per cent. solution of cocaine previously injected up the urethra will be found useful. The urethra is then thoroughly mopped with dry cotton-wool fixed in a stilet and examined by the electric light. The exact limit of the inflammation can then be clearly seen. It is, as a rule, quite five inches from the meatus; it may be four inches even so early as the third day of the disease. The implicated surface is at once to be recognized by its swollen, bright-red appearance, as contrasted with the rosy color of the healthy urethra. Occasionally distended vessels can be seen coursing over the inflamed surface. It is important not to pass the endoscope needlessly far beyond the posterior limit of inflammation, which is usually sharply defined. The diseased membrane should be now carefully remopped with dry cotton-wool, so as to remove every vestige of secretion and have a perfectly clean surface. A mop of cotton-wool on a stylet, and charged with a solution of silver nitrate (ten grains to the ounce of water), should then be passed down the endoscopic tube and thrust through its distal aperture. The tube and the mop are then withdrawn simultaneously. By this means the walls of the urethra contract upon the mop and are thoroughly moistened by the solution. For the two inches of the urethra near the meatus a fresh mop is used, so as to completely saturate this portion of the passage, in which the disease commences, and where also the inflammation is most intense. The patient will always complain of slight burning pain for a few minutes; but this gradually passes off, and in ten minutes or so he feels quite comfortable. He is recommended to take a hot bath at night and to remain quiet, in bed if possible, the following day. The diet is regulated as usual. A saline purgative, with an alkaline or copaiba mixture, is given internally, and the patient is instructed to use a mild cleansing injection, such as Condy's fluid (one drachm to the pint).

Dr. Cotes has tried his plan successfully upon forty-two patients. He states that it is not indicated in cases in which the meatus is too small to admit the endoscope, or in cases in which the inflammation extends back beyond the range of vision or the reach of the applicator. The method, as will be seen, includes the use of copaiba and injections. It requires skill and care in its application, but seems simpler and apparently more effective than the antiseptic irrigations.

A NEW SKIN DISEASE.

New remedies have so far outstripped the discovery of new diseases that it is with a certain sense of relief that we record an attempt to diminish the disproportion. Dr. Savill has observed (*The British Medical Journal*, December 5, 1891, and January 9, 1892) a new form of epidemic skin eruption which has decimated the aged population of several London workhouse infirmaries. The characteristic feature of the eruption is the desquamation or exfoliation of large areas of epidermis. An illustration showing an almost complete cast of the hand indicates to what extent this shedding of the skin may go. The disease begins as a papular, papulo-erythematous, erythematous, or ringed eruption, and becomes confluent in from three to eight days. In some instances the rash strongly suggested rötheln, but there was absence of pyrexia, and these cases, like the others, soon took on either an eczematous appearance, or one more like the descriptions given by Wilson of pityriasis rubra, according as the dermatitis became moist or dry.

In some instances there were vesicles on some portion of the surface, and when the face was the chief part involved a swelling, often sufficient to close the eyes, and in other parts as well where there was an abundance of loose cellular tissue the tumefaction caused a strong superficial resemblance to erysipelas.

The disease appeared to be confined to certain institutions, had a decided predilection for the aged infirm, and ran a more or less definite course of seven or eight weeks. Twenty per cent. of the inmates were attacked, and a number died. The eruption showed a proneness to start on exposed parts, as the face and scalp, though equally often on the arms.

Post-mortem examination in the fatal cases revealed nothing to account for the affection, and bacteriological investigation, so far as it has gone, showed the presence of a diplococcus, but whether a new one or only a modified form of the staphylococcus has not been determined. Albumin was found in fifty per cent. of the cases. Since those who had opportunity to observe the cases could not make a positive diagnosis, we will not presume to do so; but it would seem probable from the data furnished that while the disease might be classed as an eczema of a parasitic and probably, of a contagious nature, from the extent and intensity of the inflammation, infiltration, and desquamation, it would be more probably put down as a dermatitis exfoliativa.

Pityriasis maculata et circinata is suggested by the onset and duration, but this seldom becomes so confluent, never produces such extensive desquamation, clears up in

the centre of the separate patches, and does not end fatally. However, the absence of data regarding the deaths prevent an opinion being advanced as to the possibility of its resulting from preceding or intercurrent disease. One naturally turns to the influenza eruptions as a possible explanation, but it was found that few of those affected had had the grip. Pityriasis rubra is never accompanied by papules or vesicles. To be sure we do not know dermatitis exfoliativa as an epidemic disease, but it often occurs as a scarlatinal form of eruption, and we are told that many of the 163 cases observed resembled scarlatina in a measure, and relapses were not infrequent. Vesiculation is also not unusual in this disease. It seems hardly possible that any drug, such as quinine, could have produced a dermatitis in so many persons at the same time, but a single instance of the affection described could readily pass for a quinine eruption.

Whatever may have been the etiology of this strange and till now unexplained outbreak it was found, that local applications of creolin gave the best results.

A LANGUAGE FOR SCIENTISTS.

No one can doubt the utility of international scientific congresses, or that they are to the benefit not only of those participating, but of scientists everywhere throughout the world. New ideas are brought out, not only in the set papers, but also, less frequently, in the discussions; men meet and form friendships with their fellow-workers in the different departments of knowledge, and an incentive to renewed labor and more diligent study is found in this personal intercourse with workers in other countries. But there is one great drawback which is patent to all who join in these meetings, and which, so far from diminishing with time, seems only to become more and more apparent with each succeeding congress. This, of course, is the want of a common language. Some men there are whose acquaintance with the three official tongues is so familiar that they can take part in all the proceedings with ease, indifferent as to what language may be used, but they are few. The majority, and these are not infrequently among the most learned in their respective specialties, can command but one tongue, and thus two-thirds at least of what is said is lost to them. They cannot discuss a question, because they have not heard it, and if they read a paper they are unintelligible to one-half at least of their auditors. Admitting that discussions are for the most part useless, yet they are not always so, and often a thought which has flashed into the mind of the speaker, and is then and there given out, is pregnant with ideas of great value. All this is lost when the hearer understands no more of what is going on about him than if he were at a convention of deaf-mutes.

A plan was adopted in Paris during the meetings of the many congresses at the time of the Exposition, which reduced these inconveniences somewhat, yet did not, of course, obviate them entirely. Those who intended to present communications had their papers ready some time before the opening of the congress, and they were then printed and distributed to all the members before the meeting, so that they could be read, or, if necessary, translated, and their contents noted. Then at the actual meeting, instead of consuming time by reading these long, set papers, unintelligible as they would be to many of the members, the authors presented short abstracts of them, giving merely the principal heads of their argument, and these abstracts having been previously translated were printed and handed to those present at the meeting. After this all, as far as they were able, joined in an intelligent discussion. We might suggest, in passing, that this would not be a bad plan to adopt at all society meetings. It would effect the saving of not a little unprofitable wind, if we may be forgiven the uncharitableness of the remark.

In almost all the discussions of this question of language, which are always provoked by every international scientific meeting, the only solution arrived at seems to be that Latin must be rehabilitated as the mother tongue of all the sciences. It is said that the Frenchmen will never speak German, the Germans will never speak French, and neither Frenchmen nor Germans will, nor as a rule can, speak English, consequently they must all meet on the common ground of the Latin. Of course, Volapük, Esperanto, Spelin, and all the other made-up languages, which have been as persistently advocated by their inventors, are out of the question. But why not Greek? This is a more flexible and more beautiful language than Latin, equally clear and expressive, and at the same time much better adapted for use as a conversational tongue. The modern form of the language, such as is in use in Athens to day, is easily learned, readily adapts itself to the formation of new words to express modern inventions, words formed, nevertheless, on strictly classical models, and differs as little from the Greek of Xenophon or of Plato as the English of to-day does from that of Chaucer or of Spenser. We commend a consideration of the claims of Greek to those of our esteemed contemporaries who are agitating anew the subject of a universal language of science.

PARESIS OF ADOLESCENCE.

Charcot's lecture upon the subject, reported by Dr. Paul Blocq, appears in *Le Mercredi Médical*, February 10, 1892. Diffuse meningo-encephalitis, or general paralysis of the insane, was supposed earlier to belong only to adult life, and to be a disease that never attacked women. Already there are seven well-authenticated cases of paresis of adolescence, exclusive of Charcot's patient, who is a lad sixteen years of age. Among all who suffer from diffuse meningo-encephalitis there is one woman to about every ten men. In women the disease, in its earlier manifestations, bears a close resemblance to paresis appearing at the period of development. There are psychic disturbances, but no marked delusions of grandeur except certain fantastic, perverted ideas that do not require asylum treatment. The condition is one of primary dementia, often preceded by depression.

However uncertain or vague the onset from the psychic point of view, there are physical signs sufficiently characteristic upon which to base a diagnosis. Of these the most important is embarrassment of speech. When the mouth is opened there is tremor of the jaw and lips, and fibrillary shaking and trombone movement of the tongue as soon as it is protruded. Speech is labored, scanning, and confused. In disseminated sclerosis there is also scan-

ning speech, yet the syllables are distinct and easily understood. In diffuse meningo-encephalitis, the syllables of words run together, and there is a redundancy of *l's* and *r's* that give the characteristic sputtering. This peculiarity is pathognomonic and can seldom be imitated. Occasionally subjects thoroughly bromodized among alcoholics, or those suffering from paralysis agitans, will present somewhat similar symptoms of disordered speech. A little care suffices to establish a differential diagnosis. Charcot considers this condition so emphatically a pathognomonic sign of paresis, that he affirms his willingness to base a diagnosis upon it alone, even in the absence of all psychic disturbances. Next in importance is a notable awkwardness of movement, voluntary or automatic, as in walking. The gait is also peculiar. The legs are far apart, the patient falls heavily on one foot and drags the other in walking, the hands are held separate from the body, and there is a dumfounded expression of face. Vibratory tremor is often present, six or eight oscillations to the second, that is somewhat analogous to the tremor of alcoholism or exophthalmic goitre. Then come ocular troubles, inequality of the pupils, and the Argyll Robertson symptom. Toward the closing period of the disease there is more and more helplessness. Paretics then cannot walk, owing to a kind of astasia-abasia, though the dynamometric force of the limbs is in part preserved. The closing scene is that of complete dementia, the darkness of perpetual intellectual night.

The two women and the lad of sixteen, presented the day of Charcot's lecture, manifested the chief foregoing peculiarities, together with alterations in handwriting. In none had there been even mild delusions of grandeur or any melancholia, and in all there was the characteristic difficulty of speech. The boy was perfectly well as a child—bright, happy, and an apt pupil. After leaving school at fourteen, he began an apprenticeship at cravat-making, and shortly after this period his usually distinct chirography underwent a deplorable change. There was loss of memory, depression, stupidity, and general apathy. Family history revealed transient attacks of mental unsoundness in a cousin and alcoholic excesses in the father shortly before the boy's birth. This emphasizes the fact that syphilis or alcoholism may induce paresis as an inheritance. In those who suffer from paresis, Charcot considers syphilis, alcoholism, and overwork exciting causes only, and not in any way essential factors. In the boy, who had already been ill two years, paresis or diffuse meningo-encephalitis developed solely from individual constitutional defect that brought about arrest of development, manifested physically by undersize and deficient force, and psychically by the syndrome of primary dementia.

EMPLOYMENT FOR THE INSANE.

The report of a committee appointed by the Medico-Psychological Association of Great Britain and Ireland, to formulate propositions as to the care and treatment of the insane (*Journal of Mental Science*, October, 1891), contains the following suggestion regarding patients in asylums: "An essential part of the mental treatment is to distract the mind from insane ideas, and to suggest new and healthful thoughts by means of suitable employment and recreation. *Employment should be prescribed and watched* by the physician, as carefully *as any medicine*, it should be applied like medicine to the needs of each individual case, and it should be varied according to the condition of the patient and his previous history. Amusement and recreation come next in value, they should be used on the same principle as employment, and they are most useful when the patients take an active part in them, and are not merely spectators. Intellectual recreation in books, magazines, and newspapers is very important to many patients. Everything which tends to assimilate asylum to ordinary home life, and which can lessen the inevitable difference between them, is of the first importance. The whole surroundings and conditions of life in asylums should be as home-like, and as little irksome as possible; and every patient should have the utmost amount of personal liberty consistent with safety and the proper treatment of his disease."

THE DECADENCE OF THE GENERAL PRACTITIONER.

Dr. William B. Graves thinks (in the *Virginia Medical Monthly*) that the general practitioner is going to pieces. His decadence and ultimate elimination will be due partly to the use of specialism, and partly to the spread of medical charities and medical pauperism.

Dr. Graves is, we think, unnecessarily depressed. The general practitioner of the future will have to adapt himself to the new conditions of a wider intelligence and more critical spirit. He will have to be a better doctor, more learned, more experienced, less dogmatic, more thorough, more careful, and—more expensive. The day when a man can be made a general practitioner in two years, or even three, is passing away, that is all, Dr. Graves. Be cheerful and work.

News of the Week.

A Rival to the Keeley Cure.—A well-known physician of this city, heretofore in good repute, has discovered a cure for alcoholism which is better than Keeley's, and he has started an institute for treatment.

Cremation.—A bill has been introduced into the State Legislature prohibiting any disposition of the human body except by burial. This strikes a blow at cremation, and, what is more serious, at mummifying processes in mausoleums especially built for the purpose.

The Loco Weed is the name given to at least seven different plants growing on the Western plains and popularly supposed to make animals which eat it insane. Recent investigations by the Agricultural Department appear to show that the loco weeds are all in fact harmless.

Are Mydriatics Needed for the Determination of Refractive Errors.—An interesting controversy is going on between the editors of the *Medical News* and the *Post-Graduate* regarding the need of mydriatics for the determination of refractive errors of the eye. The *News* thinks them necessary, but its opponent does not; and the English language is picturesquely strained in attack and defence of the subject. The *Post-Graduate* utters this last word: "We have again consulted the instructors

in ophthalmology in the Post-Graduate School, and they again assure us that the use of a mydriatic for the determination of errors of refraction is an ancient and generally useless practice. This assertion may be ludicrous, when its truth is unknown, just as an Irishman sometimes finds Italian a heathenish jabber. Inform yourself, dear neighbor, about the best method of determining an error of refraction." In the same issue of this journal we find an article by Dr. Frank Van Fleet, in which he states that by the use of the ophthalmometer and ophthalmoscope refractive errors can be in most cases better determined than by the use of atropia in the older way.

A Pure Food and Drug Bill.—A bill has passed the United States Senate, and promises to become a national statute, concerning the adulteration of food and drugs. It makes a misdemeanor, punishable by fine and imprisonment, the introduction into one State or Territory from another of any food or drug adulterated or improperly branded. A drug, under the provisions of this act, is any medicine, internal or external. A food is anything plain or mixed, simple or compound, which is used for food or drink by mortal man. Every person who ships food or drugs from one State to another, or exposes the same for sale, must furnish samples to the agents of the Food Section of the Chemical Division of the Department of Agriculture. It will be interesting to see how this law will work in the case of patent and proprietary medicines. What, we should like to know, would constitute adulteration in the case of the Keeley Cure, or the Pinkham Vegetable Compound, or a popular porous plaster?

A Novelty in the Way of Medical Associations is the recently organized Afro-American Medical Society of this city, of which Dr. W. H. McKenley is president. The Society is composed of colored physicians, and its object is to secure closer race union, and to establish a hospital. Complaint is made that colored patients do not receive the treatment they require when admitted to the general hospitals of the city, and that, on one pretext and another, admittance has been denied at times. One of the colored physicians says: "Even when we place a difficult case in any of the hospitals of the city, we are not permitted to participate in the diagnosis of such case except as spectators. Our own cases are removed beyond our control or supervision the moment we transfer them to any of the hospitals, which is proper enough if we were permitted, as other physicians are, to participate in the general consultations and diagnoses. We have no place in the hospital service of the city, and we do not receive the courtesies and advantages that are common to members of the profession."

Physicians headed the list of suicides last year, and they have headed it every year in the last ten. This promises to be still more conspicuous this year, as in the first twelve days of the present month no less than seven physicians have committed suicide in the United States. There seems to exist no satisfactory solution for this state of affairs.

Obstetrical Science and Architecture.—In the northwestern part of this city are two maternity hospitals; one, the Sloane, is a model of all that a maternity hospital should be, and is fully equipped with everything that obstetrical science could possibly require. The other, the New York Infant Asylum, is an aged, wretched, ill-ventilated, badly-plumbed wooden building, reeking with sewer-gas, and threatening at any time to fall into the street. It has not even a pair of obstetrical forceps which can be called its own. Yet, in the past few years there have been delivered in each hospital 1,000 consecutive cases of midwifery, with only, in each series, three deaths. The results have been obtained, of course, only by great watchfulness and careful antisepsis. But they show that architecture and elaborate appliances are not absolutely essential to successful work, and that the man is greater than his environment.

An International Congress of Gynæcology and Obstetrics.—The Belgian Society of Gynæcology and Obstetrics has taken the initiative in the organization of a series of International Congresses to be held every four years in Switzerland and Belgium alternately. The first Congress is announced to take place at Brussels between September 14 and 19, 1892.

The Michigan State Medical Society announces that its twenty-seventh annual meeting will be held at Flint, on Thursday and Friday, May 5 and 6, 1892. The value of effective professional organization is too apparent to need further comment.

Forty-third Annual Session of the Medical Association of Georgia will meet in Columbus, Ga., on April 20th, 21st, and 22d. The officers are: *President*, G. W. Mulligan, M.D., of Washington, Ga.; *Vice-Presidents*, James M. Hull, M.D., of Augusta, Mark H. O'Daniel, M.D., of Macon; *Treasurer*, E. C. Goodrich, M.D., of Augusta; *Secretary*, Dan H. Howell, M.D., of Atlanta, Ga.

A Mathematical Prodigy.—*Poeta nascitur non fit.* The feats of Jacques Inaudi at the Académie des Sciences last Monday week seem to prove that the above axiom is applicable to arithmeticians as to poets. Inaudi is a native of Piedmont, twenty-four years old, and of short stature. The size of the head is rather below the normal standard, the forehead is very lofty and straight, and the facial angle well developed. That his calculating powers are of a very high order, and his memory quite extraordinary, is proved by the following experiments performed before the assembled academicians. Facing the audience and consequently turning his back to the blackboard, M. Darboux writes on this latter the following figures: 4,123,547,238,445,523,831 and 1,248,126,158,234,128,910, and, after having called them out, asks Inaudi to subtract the one from the other. Inaudi repeats the numbers quite correctly, closes his eyes firmly, and immediately answers correctly. M. Darboux then puts the following question: "What number is it whose square and cube added together equal 3600?" In less than two seconds Inaudi replies "15." M. Poincarré then gives the following problem: "Give the square of 4,800, subtract one and divide by six." At the same time, M. Bertrand asks: "On what day of the week did March 11, 1882, fall?" Inaudi replied immediately, "The 11th of March, 1882, was a Monday, and a person born on that day would have lived to-day, had he survived, so many hours, minutes, and seconds." (All these figures were found correct.) "The result of the calculation proposed

by M. Poincarré is 1960." These astonishing feats of rapid calculation greatly surprised the scientific men present, and the Academy forthwith appointed a committee, composed of MM. Darboux, Poincarré, Charcot, Chauveau, and Tisserand, whose duty it will be to report on the mnemotechnic methods employed by this wonder of the nineteenth century. It is said that Inaudi can hardly read or write.—*Lancet.*

Tuberculous Milk.—A bill has been introduced into the State Senate authorizing the Board of Health to take steps to prevent the sale of the milk of cows afflicted with tuberculosis.

Female Doctors and the Virginia Legislature.—Some weeks ago, a bill passed the House of Delegates of Virginia, requiring that one of the staff of physicians of each of the insane asylums of the State shall be a female; but when the bill came to the Senate it was defeated by a large majority.

The Pan-American Medical Congress.—The Medical Society of the County of Kings has endorsed the Pan-American Medical Congress, and appointed the following committee to co-operate with its officers: Drs. J. H. Raymond, *Chairman*, Alexander J. C. Skene, and Alexander Hutchins.

Reviews and Notices of Books.

A System of Practical Therapeutics. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Assisted by Walter Chrystie, M.D., Late Physician to St. Clement's Hospital, and Instructor in Physical Diagnosis in the University of Pennsylvania. Vol. I. "General Therapeutic Considerations," "Prescription Writing." "Remedial Measures other than Drugs," "Preventive Medicine," "Diathetic Diseases and the Diseases of Nutrition." Illustrated. Pp. 1052. Philadelphia: Lea Brothers & Co. 1891.

In the English language there are systems of medicine, of surgery, of obstetrics and gynecology, and of almost every branch of the healing art except therapeutics. In the study of a disease the one element that is most important—its treatment—is most often given the least attention. Elaborate treatises are written on pathology and diagnosis, and the treatment dismissed with a few words, and these often with so little detail that they are unpractical to the mass of practitioners. Furthermore, the progress in therapeutics, with the introduction of an immense number of new remedies, call for a complete work on the subject. Such a task Professor H. A. Hare has taken on himself. He has the assistance of the best medical writers of the age. The volume in hand opens with a chapter on "General Therapeutic Considerations," by Horatio C. Wood, M.D., LL.D. He discusses the principles that underlie the modern method of therapeutics, exposing the follies of empiricism and homœopathy, and showing the true scientific method that knows no dogmatic law. Then comes the important subject of dosage, a chapter that all could read with profit. He closes with an excellent and concise set of general rules for the combination of drugs in writing prescriptions. This subject is more elaborately discussed by Joseph P. Remington, Ph.M., who is the authority on the subject. He gives sufficient pharmacy for a physician to get an insight into the subject, a subject of which the majority of physicians are amentably weak. Electro-therapeutics is given nearly one hundred pages, the excellent treatise being written by Professor A. D. Rockwell, A.M., M.D. His remarks on dosage of electricity and on its application in gynecological troubles are sound doctrine too often unheeded.

John K. Mitchell, M.D., describes Professor Weir Mitchell's rest cure for neurasthenia and hysteria with such simplicity and detail that any reader could intelligently carry it out. In the prescribed cases it is beyond question of great value. Swedish movements and massage is explained, with profuse and excellent illustrations, by Benjamin Lee, A.M., M.D., Ph.D.; and Edward Mussey Hartwell, Ph.D., M.D, writes on "General Exercise."

On "Climate" Dr. S. Edwin Solly contributes one of the most valuable papers in the book. It is short, concise, and relates almost entirely to America in its application, and shows how and where to treat disease by means of climate. It is of value, too, in being explicit in saying just where and when to send any given case.

Dr. Simon Baruch's article on "Hydrotherapy and Mineral Springs" is likewise of exceptional value. The Germans have learned the value of hydrotherapy, to their immense advantage, and Americans should not be slow in following in their footsteps.

In that part of the work devoted to preventive medicine Dr. Henry B. Barker writes on "General Sanitation;" George M. Sternberg, M.D., on "Disinfection;" J. William White, M.D., on "Antisepsis and Asepsis;" I. Burney Yeo, M.D., F.R.C.P., on "Nutrition and Foods, including the Treatment of Obesity and Leanness." Under Diathetic Diseases and Diseases of Nutrition are these papers: "Tuberculosis," by Solomon Solis Cohen, A.M., M.D.; "Scrofulosis and Rachitis," by Walter Chrystie, M.D.; "Acute and Chronic Articular Rheumatism, Rheumatoid Arthritis, and Gout," by James Stewart, M.D.; "Scurvy," by John B. Hamilton, M.D., LL.D.; "Diabetes Mellitus," by Frederick A. Packard, M.D.

The work is distinctly therapeutic, and the subjects of diagnosis, pathology, etiology, etc., are only discussed as necessary to intelligently understand the *rationale* of treatment.

Lehrbuch der Ohrenheilkunde. Von Professor Dr. Victor Urbantschitsch. in Wien. Dritte vermehrte Auflage. Wien and Leipzig: Urban & Schwarzenberg. 1890.

A Practical Treatise on the Diseases of the Ear, including a Sketch of Aural Anatomy and Physiology. By D. B. St. John Roosa, M.D., LL.D. Seventh Revised Edition. New York: William Wood & Co. 1891.

Deafness and Discharge from the Ear; The Modern Treatment for the Radical Cure of Deafness, Otorrhœa, Noises in the Head, Vertigo, and Distress in the Ear. By Samuel Sexton, M.D., assisted by Alexander Duane, M.D. New York: J. H. Vail & Co. 1891.

The name of Professor Urbantschitsch needs no introduction here, as it is already well known to all those familiar with the more modern progress of otology. The present third edition of his well-known treatise on the diseases of the ear reflects the author's thorough knowledge and conversance with every subject pertaining to otological literature and work. It is, in fact, only another witness of the careful and painstaking work of our German *confrères* in the compilation of material relating to every subject to which they turn their well-trained minds. The present volume should rank high in its position among the works on otology, and as a book of reference has an especial value. In its perusal we note with much pleasure the absence of long drawn-out histories of cases, with which so many authors pad out their works. The different subjects are treated of in a short, practical, yet thorough manner, the references to the literature of each being remarkably exact and complete. The author

gives us, in Chapter VII., a clear and concise treatise on the labyrinth and acoustic nerve, the portions relating to the anatomy and physiology of these organs being especially worthy of mention. The cuts illustrating this part of the work are also of much interest and will afford valuable aid in the study and comprehension of this but vaguely understood region. Deaf-mutes and deaf-mutism are treated of at length, with especial reference to the educational measures for these unfortunates. The last portion of the work, where injuries to the ear, of various kinds, are considered from a medico-legal stand-point, will be found not only instructive reading, but will also demonstrate the importance of a thorough knowledge of such matters as a protection to the physician.

In Dr. Roosa's work, the seventh edition of which finds mention above, we note quite a number of changes and additions, especially those in relation to diseases of the nose and throat to the ear, and certain operative procedures on the drum-head, ossicles, and mastoid process. This work on the ear is so well known and has been so extensively read, that it would seem almost unnecessary to mention it in detail, especially in so limited a review. The book is one every aurist should possess; indeed, every practitioner of medicine would do well to read it carefully, since it presents an immense amount of valuable and practical knowledge of the diseases of the ear. The latest edition of Dr. Roosa's book is furnished with a new and more elaborate index, and the numerous illus trations leave nothing to be desired.

Dr. Sexton's little volume, just issued, will doubtless be hailed with pleasure by all interested in progressive otology, for, although it considers but one subject, that one represents the most important step in advance recently undertaken in the surgical treatment of ear diseases. The author's work in the direction of improving the hearing in cases of chronic catarrhal otitis media, and the discharge in the numerous class of intractable cases of chronic purulency of the middle ear, has excited much attention now for some years past, and the present monograph is simply a compilation of his experience in this field of aural surgery. Sexton's methods of performing the operative removal of the drum-head and ossicles, or their remains, are well known and need not be discussed in detail here. The work before us is interesting and valuable, especially as a review of the indications for this procedure and a synopsis of the results obtained through its performance. As for the latter, we are told that they are, if the operation be conducted with care, highly satisfactory, and also in cases of chronic purulent otitis media with caries of the ossicles, adhesions, etc., in the tympanic cavity. In the cases of so-called dry, catarrhal inflammation of the middle ear, with thickening of the drum head and rigidity of the ossicular chain, the operation would also be indicated, since other treatment has shown itself without avail in such cases. Annoying tinnitus, vertigo, etc., due to certain morbid conditions of the middle ear and its sound-transmitting mechanism, are also indications for this operation. The instructive cases given show the improvement in both the subjective and objective conditions. The operation is without danger, but requires considerable skill, steadiness, and knowledge of the anatomy of this region on the part of the operator.

It might be of interest in this connection to note the views of Urbantschitsch and Roosa, in their above-mentioned works, in respect to the value of this operation. In chronic purulency of the tympanum, especially when confined more or less to the attic, Urbantschitsch recommends warmly the thorough removal of all obstructing and diseased tissues, ossicles, etc., and states that such procedures, in his hands, have been followed by excellent results. In cases of fixation of the ossicles in chronic middle-ear catarrh, he considers the removal of the ossicles also indicated and useful. In twelve cases treated in this manner the results were most satisfactory. Roosa, on the other hand, cannot be said to favor its performance in cases of chronic catarrhal otitis media, although he admits that it may be a sound surgical procedure in chronic suppurations, or as a means of removing necrosed bones and morbid tissue.

Wood's Medical and Surgical Monographs. Consisting of Original Treatises and Reproductions, in English, of Books and Monographs Selected from the Latest Literature of Foreign Countries, with all Illustrations, etc. Vol. XII., No. 3. New York: William Wood & Co.

The number of this well-known series for December, 1891, is taken up entirely with a translation of Dr. Otto Roth's "Modern Materia Medica," revised by Dr. Gregor Schmitt. The first part consists of a list of the various remedial agents, grouped according to their physiological and therapeutic actions, and this is followed by a consideration of the drugs and other remedies as regards their physiological action, therapeutic use, and dosage. Parts III. and IV. contain lists, with dosage, of remedies used hypodermically and by inhalation. In Part V. the various diseases are taken up in regular order, and the appropriate treatment—hygienic, dietetic, and medicinal—for each is succinctly stated. A therapeutic index completes the treatise. A specially valuable feature of the work is the large number of formulæ which it contains, wherein the most suitable mode of administration of each remedy is indicated. The book is thoroughly up to the times, and treats of the latest additions to the materia medica as well as all the old and standard remedies. This number contains also a general index to Volume XII.

Wood's Medical and Surgical Monographs. November Number. Contents: "The Practice of Hypnotic Suggestion, being an Elementary Hand-book for the Use of the Medical Profession" by George C. Kingsbury, M.A., M.D.; "A Practical Manual of the Bacteriological Analysis of Water," by Dr. Miguel. Pp. 267. Illustrated. Price, $1. New York: William Wood & Co.

The prominent position which hypnotism has taken in medicine, and the undoubted good of which its use is capable, makes it a fit subject for careful study. The article in the November monograph is most complete, and gives all the details which make it possible for the general practitioner to practise it. The second monograph, on the "Bacteriological Analysis of Water," is by Dr. Miguel, chief of the micrographic service of the municipal observatory of Montoouris. He is an authority on the subject; his article is clear and concise, and the technique easily carried out. Both articles are profusely illustrated.

Age of Domestic Animals. Being a Complete Treatise on the Dentition of the Horse, Ox, Sheep, Hog, and Dog, and on the Various other Means of Determining the Age of these Animals. By Rush Shipper Hinderkoper, M.D., Veterinarian (Alfort, France); Professor of Sanitary Medicine and Veterinary Jurisprudence, American Veterinary College, New York; Lieutenant-Colonel and Surgeon-in-Chief National Guard of Pennsylvania; Fellow of the College of Physicians, Philadelphia, etc. Illustrated with 200 Engravings. Pp. 217. Philadelphia and London: F. A. Davis.

The title of the book is an index of its contents. There is a mass of information that makes it not only valuable to horse and stock dealers, but also to physicians. An entertaining chapter is devoted to the teeth of man. The work is profusely illustrated.

Cancer Caustic.—Heat sulphate of zinc till water of crystallization is driven off and the sulphate falls into a powder. Add pure sulphuric acid to any desired thickness, that of mortar being preferable. It can be used in all cases unamenable to the knife, and leaves a granulating surface that heals with surprising rapidity.—Stephen Smith.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting. February 22, 1892.

GEORGE HENRY FOX, M.D., PRESIDENT, IN THE CHAIR.

Case of Complete Non-menstruation.—DR. H. W. MITCHELL read the history of the case, the patient being an Irish girl, twenty-four years of age, of healthy parentage. Had always been healthy herself, except shortly after her arrival in this country, in 1888, when the remarks of her working companions about the dire results of missing the periods led her to worry and thus brought about an anæmic state. Her good health returned when Dr. Mitchell assured her that there was no basis for worry, and she had remained well since. She had never menstruated, had no pains, no "show," no vicarious menstruation. The genital organs were normal so far as could be determined by digital examination.

DR. MESSENGER knew a married woman, well formed, weighing nearly two hundred pounds, in good health, who had never menstruated. She enjoyed the sexual act, she said, and had never noticed that it was periodically stronger. The labia appeared somewhat smaller than in women of her size.

DR. COLLINS had seen two women who had never menstruated. One had been under his observation for three years, was married, aged about twenty-eight, of good health, genitals well developed. He supposed that in non-menstruating women there was some abnormality in the tube. There were many cases on record.

Treatment of Epidemic Influenza.—The discussion on this subject, begun at the last meeting, was continued. Three papers were read, one by Dr. Burrall, one by Dr. Dessau, and one by Dr. Satterthwaite. In the absence of the author the Secretary read Dr. Burrall's. He said that as he had seen influenza it had appeared under two principal types, the catarrhal and the neurotic. In the catarrhal variety the general indications were, first, complete rest; second, the best nursing; third, very careful medical attendance. These measures were to preserve the patient's force. Watchful attendance on the part of the physician was important, for the disease was an uncertain one, liable to sudden fluctuations and complications which might demand timely aid. One's therapeutics would be likely to depend upon the view he took of the pathological process. Since he had become acquainted with the views of Dr. Leaming regarding plastic exudation in the pleural cavity he had found an explanation for many varieties which formerly he regarded as pulmonary. He now found fewer cases of pneumonia or subacute œdema. In accordance with these views, antiplastic remedies were called for in the catarrhal form. In the milder form with bronchial catarrh he had the patient remain in bed, gave an alterative of calomel, pulverized rhubarb, and extract of hyoscyamus in capsules; applied oil of turpentine and olive oil, one part to two, on the posterior thorax; also made a mixture for internal use of muriate of ammonium, chlorate of potash, extract of belladonna, sirup of sanguinaria, sirup of licorice root, and oil of wintergreen. In severer forms he gave tincture of nux vomica, infusion of digitalis, perhaps nitro-glycerine and quinine. He also made judicious use of alcoholic stimulants. Where there was severe plastic exudation he gave at the outset thirty grains of calomel, which was not necessarily a cathartic under these circumstances, but an antiplastic.

In the neurotic form he enjoined rest in bed, gave calomel and rhubarb at the commencement of the disease, and administered phenacetin and salol. After two to four pills of the latter had been taken, relief generally followed. Perhaps phenacetin would do as well alone without the salol. The author suggested that possibly a different microbe would be found for these two forms, the catarrhal and the neurotic.

DR. S. H. DESSAU said that while he agreed with the statement made at the last meeting by Dr. Delafield, that there was no specific for this disease, yet he did believe there was a rational treatment which could be based upon its causation and natural history. He did not accept the idea that the duration of the disease could not be shortened. Like in other epidemic diseases, or those of germ origin, he thought our therapeutic measures would help eliminate the poison, shorten the duration, and prevent complications. The various types of epidemic influenza were, he thought, due to varying doses of the poison or vulnerability of the subject.

The author attributed the primary catarrhal effects to the growth of bacteria upon the mucous tissues, and the following depressing influence upon the nervous system to the ptomaine or toxine circulating in the blood. The idea of an eliminative treatment involved the aiding of the system in getting rid as rapidly as possible of the toxine, and at the same time relieving the intense congestion of the mucous membranes, fever being reduced as a matter of course. In accomplishing this object there was no plan better than that employed by nature, as shown in the natural termination of the disease, namely, by perspiration. The patient should be ordered to bed, and any of the ordinary means of inducing diaphoresis might be employed, but the author preferred an infusion of eupatorium or boneset. Steep half an ounce of the dried herb in a coffee-bowl of boiling water, strain, give a wineglassful every half hour. Being bitter, it was not readily taken by children. In them he preferred tincture of aconite, drop or half-drop doses hourly; or liquor ammonia acetatis and spirits of nitrous ether alone or combined. Put hot bags at the feet, lay on plenty of bedclothes. Diaphoresis relieved not alone fever, throat symptoms, and cough, but also nervous depression. He also called upon the poison-destroying function of the liver by giving calomel in small doses, say one-tenth of a grain tablet triturate, every hour. for eight hours, in the adult, subsequently every three hours until the bowels moved freely.

The author was of the opinion that the entire list of coal-tar products employed for the reduction of fever were therapeutically injurious in the treatment of germ diseases that were self-limited in character. While reducing temperature and causing diaphoresis, they also retarded metamorphosis of waste tissue, which in all probabilty became an additional poison to that already being produced by the germs of the disease, hence the nervous depression frequently following their use.

As a cough sirup he gave a combination of Begbie's mixture of citrate of potash and Ambergier's sirup of lactucarium. For occipital headache, muscular tenderness, and certain other nervous symptoms, he gave nitrate of silver, adding five drops of a one per cent. solution to two fluidounces of water, of this giving one drachm every two hours. Among heart tonics in the aged, etc., he preferred coca wine, or caffein to digitalis. During convalescence he gave. as a nerve tonic, compound tincture of chamomile. The patient should not go out until danger was quite over.

The Grip as a Cerebro-spinal Affection.—DR. THOMAS E. SATTERTHWAITE devoted his paper to a consideration of the nature of grip. He referred to the papers read at the last meeting of the Society, also to one by Andral concerning the epidemic of 1837, as proof of the complexity of the symptoms. He asked, how, then, were we to group all of these different morbid phenomena under one heading when the lesions, or, at any rate, the symptoms, indicated a rhinitis, a laryngitis, or a bronchitis; a pneumonia, pleurisy, or pericarditis; a gastritis, enteritis, or cystitis; a meningitis, cerebral or spinal; or a neuritis, peripheral or central?

The task, he said, was not too great. Althaus had asserted that these phenomena could be explained by an

inflammation of the medulla oblongata, and Dr. Satterthwaite thought it was not at all unlikely that he was right. At any rate, what little evidence had come in the line of pathological anatomy appeared to be corroborative of this view, and indicated that vaso-motor paresis or paralysis occurred. Here was a large field for pathological research. A study of epidemic cerebro-spinal meningitis seemed to show a close alliance between it and severe neurotic forms of influenza. Incidentally it might be mentioned that the two diseases prevailed simultaneously in Europe in 1837, and continued to prevail together until 1850

The author had himself seen the various neurotic symptoms of influenza which he thought pointed strongly to a central origin. In a mild case nervous symptoms were slight. There was a little dizziness, often without fever, a faintness, dyspnœa, mental depression, great lassitude. These cases were like the so-called abortive forms of cerebro-spinal meningitis. In another class of influenza cases there was suicidal tendency or grave mania. Sometimes, after the neurotic phenomena had passed, there was so-called relapse, which might manifest itself in parts most vulnerable for the time being, as the nose, tonsils, etc.

The author thought that another evidence of the disease being an affection of the nervous system was to be found in its changed type with each return from year to year.

Prophylaxis against Epidemic Influenza.—Dr. W. L. Stowell briefly outlined the history of epidemics of influenza in its bearings on prophylaxis. There had been about thirty epidemics of the disease the past three hundred years. From the histories of these epidemics, particularly the last ten, we ought to be able to learn a great deal about its contagious nature, and to combat its spread from place to place. It had been attributed at different times to the influence of the heavenly bodies, changes in temperature, lack of moisture in the air, volcanic eruptions, the influence of spores, etc. Since 1847 it had been attributed to a specific germ, or, at all events, to a material poison. But the specific germ had not, so far as Dr. Stowell was informed, yet been discovered or proven. Whatever poison was the cause of the disease, it evidently travelled from city to city, from country to country. Recent epidemics had usually been traced to Central Asia. They spread faster than the earlier ones, which was apparently due to the increased facilities for travel. There were instances going to show that the wind alone might carry the poison, as during an epidemic in England a vessel came to port with no cases whatever on board, yet within twenty-four hours, and before any communication had been had with land, one hundred and sixty cases developed.

The period of incubation seemed to be, according to Dr. Stowell's observation, about thirty-six hours. Believing that the disease was contagious, he thought the schools should be closed while the epidemic was at its height. See that the kidneys performed their function, let persons take a small amount of calomel, avoid taking cold, exposure during perspiration, and lowering the vitality.

Treatment of the After-effects.—Dr. J. Leonard Corning's experience had been limited chiefly to the treatment of the after-effects, especially nervous depression. He had tried a novel method in two cases of melancholia following grip, putting the patients into compressed air, one twice a day, the other once a day, for a week or ten day. He also gave absinthe.

Dr. Messenger had often found a congested condition of the liver, spleen, and perhaps also of the kidneys, and had observed that such patients were much benefited by benzoate of soda and salicylate of soda. He also resorted to diaphoretics and cardiac and nerve stimulants.

Dr. W. A. Fanning had seen attacks cut short by gelsemium, say two or three drops of the concentrated tincture every two hours. It did not preclude other treatment also.

Dr. Joseph A. Monell had found sulphite of sodium of great value in grip—he used it in the proportion of two drachms in four ounces of water, the dose being a teaspoonful every two hours. He also employed chlorate of potash in the usual doses, and ordered the patient in bed.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 15, 1892.

S. B. W. McLeod, M.D., President, in the Chair.

Annual Address of the President.—Dr McLeod said that inasmuch as his predecessor in office had treated in his annual address of the medicine of the past, and recently another distinguished member of the profession had pictured the medicine of the future, he would attempt to briefly portray some of the conditions of the practice of medicine at the present time. In practising medicine to-day we had to bear in mind that the medical knowledge of the laity had greatly increased the last few years. Except, however, in the application of preventive medicine or measures, little advance could be expected of the public than in the direction of nursing, the application of domestic remedies in fevers, and general shrewdness in meeting surgical exigencies. Exact knowledge was always exclusive. Physicians could not stop to reason with men who were unacquainted with the underlying facts on which the reasoning was based. But the people had ceased to look up to the medical profession with the old time awe and deference; they had learned to know better the duty of the profession to the public than the duty of the public to the profession.

A peculiarity of our people which influenced the practice of medicine was impatience, and intolerance of pain. To these facts might be ascribed the common resort to analgesics and cosmetic medication. Popular interest had also been awakened in certain diseases, such as diabetes and tuberculosis, which now taxed the doctor's skill in high degree. An important medical feature of the day was mental strain and nervous disturbances of all sorts. Excesses of every kind gave rise to premature decay. Mental aberration was very common. In fact, all nervous diseases were on the increase. The multiplication of asylums for the insane was witness for this painful truth. Dangerous cranks and murderers were also outcomes of our times. Shrewdness was a leading characteristic. The spirit of competition was ripe. Designing men were applying the advance in medical science to the promotion of selfish schemes, to the multiplication of drugs, adulteration, false representation. There was a multitude of imaginary sick persons who were breaking down their constitution by taking too much physic. Such people, prompted by the wiles of the charlatan, threw themselves into the arms of death by the very means by which they hoped to escape.

Another characteristic of our time was the presence of the money making spirit which insinuated itself everywhere. No young man should deceive himself and study medicine with a mere view to making money. Science and money did not go together. The President thought we should entertain no idea of trying to protect our business against new comers. Nor should such words as boycott or trade's union be heard among us. Medicine was not a money-making business, although the one engaged in practising the art was entitled to get from it a living. The extremes of medical charity constituted one of the degrading influences of the day. According to the latest printed statements which he had seen, one half the people of New York City received medical treatment gratuitously.

In suggesting measures for the correction of some of these evils, the President said physicians should quietly influence the people to employ only the regular profes-

sion; they should discourage the use of drugs for every ill; induce the people not to use drugs except by prescription, or as otherwise approved; parents, guardians, and teachers should exercise their influence in keeping the young from falling into the hands of schemers and advertisers. The profession should announce ex-cathedra the true principles of medical science in opposition to error.

He would deprecate all attempts to limit the number of young men entering the medical profession. There was always room for honest endeavor in the interests of the human race. When the young aspirant for a degree had been taught the various branches of medicine, his education was still incomplete until he had studied ethics. He should live up to the Code of the American Medical Association, which was also that of the County Association.

Clinical Examination of Urine, with Description of a New Case of Apparatus.—Dr. Austin Flint showed the case, demonstrated the examination of urine for sugar and albumin, and made some remarks upon the examination of the urine by each physician. It had seemed to him, for some years, desirable that there should be a portable apparatus or case, for the examination of urine at the bedside, in the possession of every physician. As long ago as four or five years he had given a description to Mr. Stollman, of the firm of Tiemann & Co., of a proposed case of apparatus but which, owing to strikes and other disturbing influences, had not been completed until recently. In having the apparatus made he had borne in mind that nothing was more important than to simplify it as far as possible for the clinical examination of urine. Of course, it was impossible to make a microscopical examination at the bedside. But to test for sugar and albumin, and to arrive approximately at the quantity of these ingredients in a given volume of urine, he had found to be quite practical.

The necessary instruments were all contained in a hard rubber box which could be put into the overcoat pocket. It contained a small alcohol lamp, about half a dozen small test tubes, two tests for albumin, two for sugar, reaction-papers, pipette, graded volumetric tube, urinometer, etc. The test liquids were furnished by Dr. Squibb. For clinical purposes he regarded Sir William Roberts's test for albumin as best, consisting in the use of pure nitric acid, one part, saturated solution of sulphate of magnesium, five parts. The control test was by heat.

For the sugar test he employed the published formula of Dr. Squibb, the agents used being Rochelle salt, caustic soda, sulphate of copper, and water. There might remain some doubt where the quantity of sugar was very small, and in that event one could resort to the carbon-dioxide or fermentation test, using a small piece of Fleischmann's yeast. A little time had to elapse before the change would take place.

Dr. Flint impressed the value of quantitative tests for sugar and albumin, and also for urea, carried out in such a way as to be reasonably accurate and at the same time easily applied. For determining the quantity of sugar in a given amount of urine, he knew of no simpler way than that of Roberts. That is, take the specific gravity of the urine to be tested, note the temperature, then put into it a suitable amount of yeast, allow fermentation to go on for twenty-four hours. Often twelve hours was long enough. At the end of that time again test the specific gravity at the same temperature, the difference between the specific gravity on the two occasions would closely approximate the number of grains of sugar per fluid ounce in the urine. In a test specimen he had found the specific gravity taken twelve hours before to be 1.035; taken after fermentation it was 1.012. Twenty-three, therefore, represented the number of grains of sugar which the urine had contained per ounce. In other words, about 4.6 per cent.

Dr. Flint had long thought it desirable that there should be a method universally accepted for clinically estimating the volume of albumin to a given quantity of urine. He knew of no better way than to use a graduated tube with one hundred as the highest mark, which should represent the quantity of urine. Then boil, add a little acetic acid, after the urine cooled shake it so as to break up the albumin, then let it stand, say twelve hours; when the height of the albumin deposited at the bottom of the tube would show its volumetric relation to the urine.

For testing the amount of urea, he employed Dr. Doremus's apparatus, which was very simple and at the same time accurate. Caustic soda and bromine were used.

The speaker mentioned how difficult it was to collect all the urine of a patient during twenty-four hours, yet how necessary. But where this could not be done oftener than once or twice, perhaps, he recommended the frequent examination of the urine passed at different times of the day. As a rule, that passed in the morning was the best sample, but in the case of diabetes this often contained no sugar, while that passed after meals showed a considerable amount.

Drs. Herman M. Biggs and C. A. Doremus gave further emphasis to the author's views regarding the need of a case containing all necessary apparatus for making an examination of urine at the bedside, of the need of frequent examinations, and their greater value as compared with one or two which might be made with greater exactitude, etc.

Dr. Henry exhibited two specimens of blue urine obtained from patients to whom he had administered methyline blue for cystitis. Besides rendering the urine blue, or greenish-blue, the medicine had proven more efficient than any other in these two instances, in relieving the symptoms for which it was administered.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 11, 1891.

H. M. Biggs, M.D., President, in the Chair

Large-celled Indurative Hyperplasia of the Lymphatic Glands.—Dr. George P. Biggs presented specimens of the above. The specimens had been removed from a boy, fourteen years of age, who had been admitted to the New York Hospital on July 10th, with a history of development of these nodules after an attack of scarlet fever ten years before his admission. A small nodule had first appeared at the angle of the jaw on the right side, which had grown slowly and interruptedly up to one year ago, since which time the growth had been more rapid. The patient's general health was good and the growths were not painful. Examination at that time showed a lobulated tumor, measuring 3 ctm. antero-posteriorly and 2½ ctm. vertically. It was not adherent to the subjacent tissues and was not tender or painful. Four days later the growth was easily removed by operation, and it was found to consist of eight ovoid bodies, varying in diameter from 1 to 4½ ctm., held together by vascular fibrous tissue. These lobules were smooth exteriorly, firm to the touch, of a gray color, and homogeneous in structure. Under the microscope they were seen to be composed chiefly of large round and spindle cells, arranged in the form of nodules, and scattered through this tissue was a reticulum of lymphatic tissue which stained more deeply than the surrounding structures. Near the centres of some of the lobules were single giant cells resembling in every respect the tubercular giant cell. No tubercle bacilli were found.

As is evident from the description, the structure closely resembles that of tuberculous lymphatic glands; but in view of the long duration of the process, and the absence of degenerative changes, and of tubercle bacilli, the specimens could not be considered as of tubercular origin, but as instances of large-celled indurative hyperplasia of the lymphatic glands. According to Ziegler, this process

consists in the transformation of normal gland-tissue into a large-celled tissue having none of the characteristics of the original structure. This large celled tissue consists of polygonal and spindle cells closely packed together, with very little inter-cellular substance. The resemblance to tuberculous change is sometimes made still more striking by the occurrence of giant cells. These hyperplastic glands are quite dense and often reach a considerable size without undergoing soft caseation, but hyaline degeneration is common.

The President remarked that the condition just described was of great interest on account of the great liability to consider the process a tubercular one, and this mistake was most likely to occur when the cervical glands in a young person were the subject of this form of hyperplasia.

Two Cases of Impacted Gall-stone.—The President presented also specimens of the above. In the first case, a patient in the almhouse, about sixty years old, came under his care about three months ago. At that time there was very marked jaundice and considerable vomiting, and she complained of indefinitely localized pain and tenderness in the abdomen. It was suspected that her symptoms might be due to impacted gall-stone, but a careful examination failed to show any enlargement of the gall-bladder or of the liver. The vomiting was soon relieved, and after three or four weeks a large cystic tumor developed in the left side of the abdomen, and its growth was accompanied by a corresponding diminution in the jaundice. The cyst was tapped twice, and a total quantity of about four quarts of a dark brownish-yellow and rather thick fluid were removed. When there was a temporary cessation in the growth of the cystic tumor the jaundice was decidedly increased. The patient's death was due chiefly to exhaustion, possibly aided by a localized peritonitis, and by the interference with the general health resulting from an abstraction of the bile from the system for so long a period. At the autopsy there was found a large cyst, the walls of which were formed by the diaphragm, the upper surface of the left lobe of the liver, the inner surface of the spleen, the outer surface of the stomach, and coils of small intestine, all matted together by exudation. The cyst contained the same kind of fluid which had been removed by tapping. On separating the adhesions on the upper surface of the left lobe of the liver a number of small openings were observed, and on cutting into the liver, it was found to be bile-stained. On the under surface of the left lobe of the liver was a very recent ulceration surrounded by adhesions. The gall-ducts were much dilated, and were surrounded by deep pigmentation and apparent necrosis. Just at the termination of the common duct in the duodenum was an impacted gall-stone, which probably completely occluded this channel during life, although at the autopsy a probe could be easily passed into the duodenum. The common duct was more than one centimetre in diameter, and just at its junction with the cystic duct was an old and rather deep ulcer which had apparently been produced by the pressure of the stone during its descent. The walls of the gall-bladder were very much thickened, and the entire inner surface was covered with a fibrinous exudation. The hepatic duct was greatly dilated, and its terminal branches communicated with the small openings found on the upper surface of the left lobe of the liver.

From this examination it seems probable that the stone having completely occluded the common duct the hepatic ducts became enormously dilated, and infection having occurred in some way, it resulted in an ulceration of the left lobe of the liver and the establishment of a communication between the ducts and the peritoneal cavity. The adhesions which developed around this point of infection resulted in the formation of the cyst, into which the bile was discharged. The cyst was probably at least four or five weeks old, and was surrounded by exudation, which had become partly organized. The fluid showed that the cyst must have been associated with the gall-bladder or with the gall-ducts. It is certainly very rare for the bile to be discharged by ulceration in the terminal branches of the hepatic duct.

The second specimen was from a woman who had been in apparent health up to the time of her admission to the hospital. She was then slightly jaundiced, but complained only of vague abdominal pains, and of feeling weak. She died suddenly on the following day. The autopsy showed a beginning of general peritonitis, the exudation being most marked in the pelvic cavity. The gall-bladder was enormously enlarged, and so great was the distention of the cystic and common ducts, that they could be easily mapped out before opening the abdomen. On making pressure on the gall-bladder, the papilla projected into the duodenum in a conical form, from one-half to three-fourths of an inch, and at its opening was a gall stone. This could be easily dislodged, and then it was found that the duct easily admitted the index finger. Had death not occurred so early in the case there would have been probably an ulceration of the papilla, and the stone would have been discharged into the intestine, leaving the duct again pervious. As in this particular case the cystic duct was not more than one-fourth the diameter of the common duct, it was fair to assume that the gall stone could not possibly have passed from the gall-bladder into the common duct, but must have been either formed in the common duct, or have passed into it when the stone was still quite small. The beginning of the hepatic duct was enlarged sufficiently to easily admit the end of the little finger.

The frequency with which gall-stones are found in the old people in the almshouse has been commented on, but no satisfactory explanation has yet been offered.

Dr. H. P. Loomis remarked that as the stone did not adapt itself well to the end of the papilla, but admitted the passage of a probe along side of it, this might account for the slight degree of jaundice.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, January 28, 1892.

Egbert H. Grandin, M.D., Chairman.

Election.—Dr. Robert A. Murray was elected chairman, and Dr. J. Clifton Edgar secretary for the ensuing year. Dr. Murray then took the chair. He asked of the members the warm co-operation which they had extened Dr. Grandin, and spoke of the benefit to the individual and to science derived from a close study and report of cases.

Vote of Thanks.—The Section gave a vote of thanks to Dr. Grandin for the able, impartial, and faithful manner in which he had discharged the duties of chairman the past two years.

Specimen from Extra uterine Pregnancy.—Dr. Florian Krug presented the specimen from one of four cases of extra-uterine pregnancy, which he had operated upon within about a week, the first of the year. He had just completed the operation for extra-uterine pregnancy in one case when the house-surgeon brought a patient in to have the uterus cleansed for supposed incomplete miscarriage. He then learned that the last period had been overdue ten days, that she then had irregular hemorrhages and pains. On examination Dr. Krug felt a tumor to the left of and posterior to the uterus; the uterus, though somewhat enlarged, yet empty. He made the diagnosis of extra-uterine pregnancy, although the other surgeons present disagreed with him, believing there was more likely a fibroid tumor. He operated four days later in the presence of these gentlemen, when his own diagnosis was confirmed. Their mistake had been due to the very thick walls of the tumor which enclosed the embryo of a

tubal pregnancy, and which, owing to their thickness and solidity, felt like a fibroid.

Dr. Edebohls thought there were three things which, when found after laparotomy, indicated tubal pregnancy although the fœtus could not be found, namely, considerable effusion of blood into the peritoneal cavity, rupture of a tube, the walls of which, lastly, were considerably thickened.

The Source of Hemorrhage.—Dr. Coe said that a cursory examination of the specimen presented would seem to show that where rupture took place in extra-uterine pregnancy the hemorrhage came principally from the sinuses instead of from the blood-vessels.

Dr. A. P. Dudley thought that where the fœtus could not be found in ruptured tubal pregnancy, a more careful search toward the diaphragm would probably reveal it at a distance, where it had been carried by the vermicular action of the intestines.

Dr. Murray remarked upon the previous history of abortion, and Dr. Krug closed with a strong plea for laparotomy as opposed to electricity, morphine injections, etc.

Baby with Congenital Dislocation at the Knee.—Dr. T. J. McGillicuddy presented a baby about twenty-four hours old, which was born during breech presentation, with the right leg against the abdomen, the knee straight, the thigh flexed; the left leg also against the abdomen, thigh flexed, the leg twisted and dislocated at the knee. The child was born without any interference. As the knee was somewhat reddened, it seemed probable, as Dr. Jewett suggested in the discussion, that the dislocation had taken place by pressure on the pubis or by some other force during labor. He was still able to subluxate the joint, but it was gradually growing firmer.

The Diagnosis of Pregnancy Between the Second and Eighth Weeks by Bimanual Examination.—Dr. Robert L. Dickinson read the paper. The number of cases reported were 33; the number of examinations made on the 33 were 45. He ventured to draw some conclusions on so small a number because they were selected cases. Cases had been excluded in which at the time of the examination drawings representing the outlines and consistency of the uterus as felt on bimanual palpation had not been immediately made, and also those which could not be subsequently followed to prove pregnancy by continued growth of the fœtus, or by well-ascertained absorption. His method of exclusion was illustrated by a typical case. A woman coming to his office would be examined, and immediately he made a record of the condition of the uterus by drawing its outline, indicating hardness or softness by difference in shading. Then perhaps a week after menstruation she would have coitus. Going beyond her next period two or three days, she would return, and examination would again reveal the state of the uterus, of which a second drawing would be made. Drawings would continue to be made at subsequent visits, say until the eighth week.

His results showed that bulging or bellying of the body of the uterus was the most constant and valuable sign, being present in nintey-six per cent. of the cases. It was most frequent on the anterior surface in forty per cent. of the examinations, but might be present alone on the posterior surface, laterally, or be present all around. Its absence in four per cent. of the cases could be explained. The next most valuable sign was change in consistency, causing elasticity or resiliency of the body, present in eighty per cent. This appeared on the average by the thirtieth day, the bulging by the twenty-eighth, though sometimes as early as the sixteenth day. The next sign was compressibility of the lower uterine segment—Hegar's sign—present in sixty-six per cent. of the examinations from the fourth to the eighth week, sometimes sooner. Still another sign was a puckering or furrowing transversely on the walls of the uterus. In one case he had been deceived in the condition of the uterus, suspecting pregnancy by its alteration in shape during examination, apparently from sexual excitement. There was also a chance of being deceived by uterine contractions, which might take place even in the young and unimpregnated, and also in the senile uterus. He very briefly referred to a part of the literature of the subject.

Dr. Coe thought it would require a great deal of practice and previous familiarity with the individual case in order to say positively that the slight changes mentioned, as occurring after the second week, were due to pregnancy. Cases in which it was most desirable to make an early diagnosis were seldom those with which one was already acquainted.

Dr. H. L. Collyer expressed great interest in the paper, owing to the fact that he had had opportunity to test the early signs of pregnancy as revealed by palpation, to which attention was first called in this country by Dr. Grandin. Dr. Grandin had supposed he was observing Hegar's sign, but afterward learned that this was something different. Having been instructed in those signs by Dr. Grandin, he had since examined three or four hundred cases, and had reached the conclusion that the most serviceable sign was elasticity at the fundus, which gave the feel as if a rubber ball had been forced out at that point. It was quite noticeable by the fifth week. Hegar's sign was absent in six to eight per cent. of the cases. The pregnant uterus was elongated about a quarter of an inch at the fifth or sixth week, nearly half an inch at the eighth. The elasticity gradually extended over the whole uterus as pregnancy advanced.

Dr. Charles Jewett thought a diagnosis of pregnancy could be made with a good deal of certainty in the second month after two or three examinations had been allowed. He thought that to the bulging, or enlargement mentioned by the author, one should join the sign of softening, for enlargement might come from a pathological cause. In the second month at least the softening became well marked. He thought a variation in the consistency of the uterus might be induced by prolonged examination with resulting contraction. The softening was of an elastic nature, not doughy.

Dr. Grandin said the paper corrobrated conclusions which he had reached in 1884. He had examined seventy five cases once, the results of which he published under the supposition that he had found Hegar's sign, but since had recognized it as something new. The conclusion which he had reached was, that under favorable conditions one could make a correct diagnosis in ninety per cent. of cases as early as the sixth week. He depended upon a group of signs—the globular shape of the fundus, bulging of the lower uterine segment, elasticity of the body. It was absolutely essential to grasp the uterus between the internal and external fingers bimanually. The subinvoluted or hyperplastic uterus could hardly be mistaken for the pregnant uterus presenting these signs.

Dr. Vineberg remarked upon the contraction of the uterus under massage; Dr. Agramonte upon the changes in the mucous membrane of the cervix and direction of the uterus in pregnancy; Dr. Edgar upon the value of a combination of the different signs mentioned; Dr. Cole upon the purple appearance of the cervix; Dr. Cushier on uterine contractions resembling the bulging shape produced by pregnancy; Dr. Murray on the same fact, stating that a further proof of pregnancy was necessary in the condition of softening named by Dr. Collyer and others, and warning one against basing conclusions on the view that all normal uteri were of the same size.

Dr. Dickinson, in closing, said he also would dwell on the value of a combination of signs as being more significant than a single one. A distinctly globular and elastic body meant pregnancy. He said Dr. Murray had properly suggested examining in such a way as to avoid causing contraction of the uterus. He would abandon the term Hegar's sign of early pregnancy, and speak of bimanual signs of early pregnancy.

The Preventive Treatment of Mastitis.—Dr. Virginia M. Davis read a paper with this title. It was based

on an experience with seven hundred and fifteen cases, most of them seen at the New York Foundling Asylum. Of this number of mothers only ten came to have pus formation in the breast. The record was better than that of maternities generally, although the mothers were seen two weeks and longer, whereas in others they were sent out as a rule before the second week. This was an important fact, for the danger of mastitis was greatest from the fifth to the twentieth day, while the gland was adjusting itself to its function. The next period of greatest danger was when the baby began to cut its teeth, and the last when it was being weaned.

There were two important points of prophylaxis, namely, to avoid if possible a break of the epithelium at the nipple, and to prevent stasis in the gland. As an application to the gland after nursing, the following was recommended: lanolin, three parts; sweet-oil, one part; compound tincture of benzoin, fifteen drops to the ounce. Other remedies might be necessary in extensive reddening. Where there was engorgement the only treatment required in some cases was light pressure by means of a roller bandage, with rubbing out of the breasts. In others the inflow of the milk was hindered by means of a tighter bandage, and Epsom salt was given to the point of mild purgation. All danger from engorgement was usually over by the fourth day. In forty cases the milk dried up without any attempt at nursing, and without difficulty. The milk very rarely flowed spontaneously from any breast which had once been allowed to become engorged. It had to be emptied by compression or expression. Where the gland became very hard, containing knotty masses, it gave relief to rub out the milk.

Where inflammation actually threatened the following indications were to be met: 1. Lessen the blood supply. 2. Encourage absorption in other directions. 3. Secure immobility and rest. 4. Relieve reflex pain and tension from accumulation of milk, and, if possible, sweep out the products. The author had relied chiefly on pressure, cold or heat, derivation, expression with suspension of lactation By applying these means intelligently early in the case, incision of the breast would be rarely called for. Cold was applied by means of the ice-bag. In two or more cases she had expressed pus by rubbing with the fingers from without toward the nipple, and had thus avoided the necessity for incisions.

Dr Grandin and the other speakers congratulated the author on the few cases which, under her management, had come to the formation of an abscess. Dr. Grandin preferred firm and equitable pressure to rubbing the breast as a means of preventing engorgement. His experience with drugs locally applied spoke little in their favor. Where pus had formed he would prefer to incise.

Dr. Collyer said the adoption of the bandage at the Maternity Hospital had driven mastitis out nearly altogether. Drs. Jewett and Murray thought a microbe was necessary for the production of pus, which meant there must also have been a lesion of the epithelium. Dr. Murray applied the bandage in all cases, but only to hold up the breasts. Dr. Buckmaster thought general surgeons failed in treating mammary abscess because usually they did not recognize the necessity for pressure in this class of cases. Drs. Edgar and Agramonte would not underestimate the value of belladonna, etc., and Dr. Agramonte also mentioned a case of grip and phthisis contraindicating the bandage. Dr. Cushier made some remarks, and the author closed the discussion.

Influenzal Insanity.—Dr. Savage says that the grip very often acts as the exciting cause of attacks of insanity in those in whom the disease is already latent. This may account for the recent unusual prevalence in this city of cranks with financial aspirations and longings.

Diagnosis of Belly-ache.—The pain in the male means appendicitis, and in the female pyo-salpinx. Treatment, open the bowels with—the knife.

New Instruments.

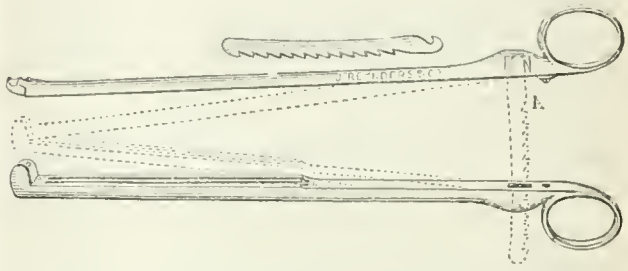
BROAD-LIGAMENT CLAMPS FOR USE IN VAGINAL HYSTERECTOMY AND DRAINAGE-TROCAR.

By BACHE EMMET, M.D.,

NEW YORK.

In a number of vaginal hysterectomies I have performed I have made use of the large Richelot clamp, modified by Doléris. In every case I have found that this clamp had one very serious defect, which must accompany every instrument of a similar principle devised for the constriction of the vessels of the broad ligaments.

In placing the blades of this instrument in position one is very desirous of having the exact top of the broad ligament, the Fallopian tube, engaged between the extremities of the blades, and, for that purpose, the finger is passed up behind the ligament to guide the blades and to see that it, and nothing else, is so included. This step can very satisfactorily be accomplished by the Doléris clamp, and, were this all, no better instrument could be called



for, since its constricting qualities are of the best. But we are now desirous of locking the blades, and in that manœuvre we are sure to again part the points, and before tightening our hold we are compelled to make a fresh exploration at the top of the broad ligament to ascertain and make sure that no loop of intestine has slipped within the branches, and also that the tube has not slipped out. To obviate this difficulty, and thereby to shorten the time necessary for such an operation, I have devised the present instrument, the special feature of which is that it acts like a nut cracker, the reverse of all other ligament clamps, closing from its distal toward its proximal end. It measures nine and one-sixteenth inches in length.

This instrument is made in three pieces, two blades and a ratchet. Its proposed application is by first introducing the male blade, carrying it up behind the ligament upon the finger of the left hand, which has preceded it and is hooked over the top of the ligament; the female blade is now passed over the anterior face of the ligament and is immediately engaged upon the male.

Everything in that neighborhood is now safe, nothing else can be caught within the jaws; they can be immediately closed and bound fast.

Should great force be required, the ratchet may be slipped in place to facilitate the gradual compression. Once the handles have been tied, it is as readily slipped out and put aside. Its hold in the handle is by means of a slight spring, which, on being depressed, quickly releases it.

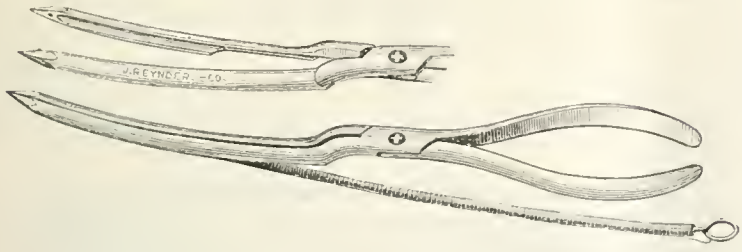
Repeated trials with this instrument show that it is as valuable in practice as it is promising in theory, and the removal of the blades during the progress of the case is even more easy of accomplishment than is their adjustment.

Note.—At the time of sending the above to press my attention is called to a device similar in principle, originating with Dr. Greig Smith.

I will here admit that this gentleman is entitled to priority in recognizing the necessity of such a contrivance, but on inspecting his instrument, which has just been shown to me by Professor T. Gaillard Thomas, I am still willing to allow my clamp to go before the world, con-

vinced that it will be found the more satisfactory of the two.

The second instrument, which I call a drainage trocar, ten inches in length, will also, I think, find a valuable



field and fill a positive want. The idea came to my mind while treating cases of pelvic abscess which I wished to drain.

Ordinarily, we puncture with a pair of sharp-pointed scissors, separate the blades while withdrawing the instrument, and seek then to insert a drainage-tube, which we willingly stitch to the vaginal wall. On such an occasion, I had punctured with an ordinary trocar, and on withdrawing it to replace it by a rubber-tube to drain the sac of pus, I was greeted by a spurt of arterial blood which compelled me to hastily pass a ligature through the broad ligament and twist up what vessels it might surround. This serving only partially to arrest the hemorrhage, I was obliged to pack the vagina firmly and forego my drainage for the time.

The present instrument not only avoids the possibility of getting into a false passage, in that it already occupies the same tract followed by the trocar, but by the steady pressure exercised in all directions it will also guard against the occurrence of hemorrhage through a wounded blood-vessel, unless, indeed, such a point chanced to face one of the eyes of the tube; but here, again, would a slight traction upon the tube displace this juxtaposition and close the vessel.

Both of these instruments are made for me by Messrs. Reynders & Co., New York.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE NEW REGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE—ANTISEPTIC PREPARATIONS OF CATGUT AND SILK AND THEIR RELATION TO WOUND INFECTION—ATROPHY OF THE TESTICLE PRODUCED BY TORSION OF THE SPERMATIC CORD—THE LATE MR. W. H. MICHAEL, Q.C.—A MEDICAL BISHOP.

LONDON, February 27, 1892.

THE appointment of Dr. Clifford Allbutt as Regius Professor in the University of Cambridge (in succession to the late Sir George Paget) will certainly come as a surprise to many. Dr. Allbutt is a distinguished physician and a clinical teacher of no small repute. He is a graduate—in both Arts and Medicine—of the University in which he now becomes a professor, and has also been an Examiner in Medicine. A few years ago, however, Dr. Allbutt relinquished all his appointments and gave up an extensive consulting practice at Leeds in order to accept a Commissionership in Lunacy. This office precluded him from private practice, and he fixed his abode in the metropolis. Dr. Allbutt now engages for a second time in a career in which he has already attained eminence. He is an original and outspoken thinker, and gave offence to many by his vigorous onslaught on some forms of specialism in the Goulstonian Lectures delivered before the College of Physicians in 1884. A man of very wide views himself, Dr. Allbutt may be trusted to worthily fill the post Sir George Paget adorned for so many years, though he is in many respects a marked contrast to his distinguished predecessor.

At the last meeting of the Medical and Chirurgical Society a communication from Surgeon-Captain Macpherson was read, in which the causation of suppuration in wounds by ligatures supposed to be aseptic was discussed. The author described a number of experiments which he had made with various materials, and said he had arrived at the following conclusions: 1. That all so called antiseptic preparations should be received with caution, and that there was good reason for rejecting such preparations of catgut. 2. Antisepsis could be obtained with certainty by boiling or steaming—the simplest, cheapest, and most efficient means of all. 3. Material thus rendered aseptic might be readily kept aseptic in bottles containing no solutions of any kind. 4. The methods of keeping ligature material aseptic by means of solutions—as suggested from time to time by various surgeons—were unnecessary. 5. The most aseptic material sold by surgical instrument makers was probably the fine undyed silk twist, untreated by any septic material.

An animated discussion followed the reading of Surgeon-Captain Macpherson's paper. The president (Mr. Timothy Holmes) said he had never experienced any ill effects from the use of catgut for ligatures and sutures, but he apparently stood alone in this optimistic view. The next speaker, Mr. Howard Marsh, mentioned a case (amputation of the thigh) in which the wound became foul within forty-eight hours along the tracks of the sutures and ligatures, and the patient ultimately died; he had no doubt that this was due to a septic condition of the catgut and of the carbolic preservative fluid. At St. Bartholomew's Hospital there was a profound distrust of material obtained from the instrument-makers for ligatures, and no house-surgeon would think of allowing anything to be used which he had not himself prepared. When properly prepared, he did not think there was any difference in this respect between silk and catgut, though he preferred silk himself. Mr. Barwell referred to the method of preparing catgut. The intestine, he said, was first partly macerated for the removal of everything except the muscular coats, and these, still containing putrefactive organisms, became converted into catgut. Catgut was then, without further sterilization, stored in carbolized oil, which was known not to be a sufficiently powerful germicide to destroy the organisms. He kept his materials for sutures and ligatures in solutions of perchloride of mercury, or of carbolic acid, for long periods before using them. Mr. Bruce Clarke said he had for several years given up the use of catgut kept in carbolized oil and employed in preference silk rendered aseptic by boiling. He described the ligature bottle in use at St. Bartholomew's Hospital. Mr. Stanley Boyd said catgut kept in carbolized oil had been for some time past condemned on the Continent, and mentioned Volkmann's case in which a patient died of anthrax produced by a catgut ligature which had originally been made from the intestines of a sheep which had died from anthrax. The material used ought to be non-absorbent, and he used silkworm gut for deep sutures and horsehair for superficial ones, and found both very satisfactory. Mr. Golding Bird remarked that those substances were the best which were least likely to be digested—such as silkworm gut, silk, or wire. Mr. Watson Cheyne said he should never think of using anything which he had not himself rendered aseptic. He had not experienced much suppuration from the use of catgut sutures or ligatures, though they might contain putrefactive organisms, but it was probable that micrococci rather than bacilli were most injurious to wounds. At King's College Hospital the materials as obtained from the makers were loosely reeled and rendered aseptic by immersion in strong carbolic solution (1 in 20). He did not agree with the author's fourth conclusion, but thought it safer to keep sutures and ligatures in some antiseptic solution. Dr. Heywood Smith said he thought silkworm gut was the best material for

sutures. Mr Bowlby then replied for the author and said that one reason why he had recommended in his paper that ligatures should be preserved in a dry state was that they were then less liable to be a source of bacterial infection, as it was well established that organisms required some moisture for their development. Silkworm gut had not been referred to in the paper as it was unsuitable for ligatures on account of its stiffness.

Mr. Bryant then read a paper in which he gave an account of a case of torsion of the spermatic cord, with strangulation of the testicle, which occurred in a boy, aged fifteen, with an imperfectly descended testicle. The case was at first diagnosed as one of strangulated hernia, but an exploratory incision revealed its true nature. Three half-twists made inward completely untwisted the cord and an attempt was made to save the testicle, as it was quite warm, but it wasted, though the wound healed kindly and the patient made a good recovery. Mr. Bryant said that at the time (1889) he thought the case was unique, but since then Mr. Nash, of the South Devon Hospital, had forwarded to the College of Surgeons a preparation which was clearly of the same kind. In both cases the affected testicle was on the left side and was incompletely descended, but in Mr. Nash's case the twisting was reported to have occurred at the external ring, while in the author's case it took place within the inguinal canal. Mr. Bryant said he felt sure that such cases had been described among those of inflammation of an ectopic testicle, and he believed that one such had been published by Mr. Jacobson in the third volume of the last edition of Holmes's "System of Surgery." Mr. Bryant was also disposed to think that many of the cases of atrophy of the testicle which had taken place after a supposed inflammation coming on without any clear cause were of this nature, the strangulation of the cord in such cases being less severe. As an appendix to his paper he gave a case of the same kind which had been reported to him by Dr. W. Keen, of Philadelphia.

A short discussion ensued. A letter was read from Mr. Bland Sutton describing a specimen of axial rotation of the right testis in an old pug dog, and the specimen was exhibited. It was remarked that cases similar to those described by Mr. Bryant had been recorded in Germany, by Bramann. Mr. W. G. Spencer said Dr. Nicalodoni had described some similar cases in *Langenbeck's Archiv* for 1885. Mr. Hulke asked if in Mr. Bryant's cases there had been a long mesorchium. He referred to a paper of his own (read before the Society in 1866) in which he had described large sacs in the scrotum, and the testes floated in and out of the peritoneal cavity suspended by long mesorchia. Dr. Herbert Spencer referred to a specimen shown by Mr. W. G. Spencer (which Mr. Spencer had stated was not really similar to Mr. Bryant's cases though somewhat resembling them) and asked Mr. Bryant if he had noticed any band at the time of the operation; he was of opinion that extravasated blood at the time of birth sometimes prevented the descent of the testes into the scrotum, and that a band sometimes remained in after-life as a sign of this extravasation. Mr. Bryant then replied and said that the testicle was only just showing through the external abdominal ring, that there was a long mesorchium, and no sign of any band.

A remarkable career is closed by the death of Mr. W. H. Michael, Q.C. He attained considerable success in two professions—those of law and medicine. For about twenty years he was in general practice in South Wales, but relinquished his large practice in order to become a barrister. While in practice he gained a considerable repute as an obstetrician, and was often consulted by his professional brethren in difficult cases. He was equally successful in the legal profession and soon obtained a large practice at the parliamentary bar — especially in matters relating to gas and water, and various sanitary questions. His legal career extended over rather more than twenty years. As another example of success in two professions may be mentioned Dr. John Wale Hicks, of Cambridge, who has just been designated as a Colonial Bishop. Dr. Hicks is a Fellow of the Royal College of Physicians, and a graduate in medicine of the University of London, though he has not been in practice for many years past, but has been a Resident Fellow at Sidney Sussex College, Cambridge.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 12, 1892.

	Cases.	Deaths.
Typhus fever	12	8
Typhoid fever	6	0
Scarlet fever	223	34
Cerebro-spinal meningitis	0	3
Measles	331	18
Diphtheria	107	31
Small-pox	1	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Plastic Bronchitis.—Dr. Józefowicz describes in the *Gazeta Lekarska* an interesting case of that somewhat rare disease, plastic bronchitis, occurring during the course of acute articular rheumatism. The patient was a student, nineteen years of age, who complained of a troublesome cough with lancinating pains in the chest. The expectoration was muco-purulent, and contained some blood and fibrin. In the course of the disease one night a sudden paroxysm of cough occurred, with copious bleeding from mouth and nose, and expectoration of flesh-like masses. Dr. Józefowicz, on examining the expectoration, found in it masses of coagulated fibrin, partly presenting ramifications, as if coming from the smallest bronchi, and partly cylindrical, corresponding with the shape of the larger bronchi. Shreds of membrane of various thickness were also found, probably coming from the largest bronchi, or possibly from the the larynx and nose. The microscope also discovered numerous pus corpuscles, epithelial cells, and red blood-corpuscles. The etiology of plastic bronchitis is not sufficiently known. Phthisis, bronchial catarrh, general debility, atmospheric influences, diphtheria, and typhoid fever are mentioned as causes of the disease, and it is also found associated with mitral insufficiency or stenosis of the auriculo-ventricular orifice. This connection existed in the present case, as, even during an early period of the rheumatic affection, both these heart symptoms were diagnosed. Another symptom to be taken into serious account was the infiltration of the lung parenchyma, which could not be referred to an existing fibrinous pneumonia. Probably it was due to an exudation of blood, or possibly of fibrin, into the pulmonary vesicles. Hæmoptysis is generally insignificant and very rarely profuse.—*The Lancet.*

Snake bite.—Dr. Kaufmann, who recently took the Orfila prize of the Paris Academy of Medicine for a memoir on serpent venoms, says that chromic acid is the best remedy for snake-poisoning. It is employed in one per cent. solution by intramuscular injection, the needle being plunged into the tissues at the point where the bite was received. In this strength, he says, the acid exerts no caustic action in the tissues, while it destroys thoroughly the toxic properties of the venom.

Medical Advertising, both direct and indirect, is growing in favor with a certain class of doctors, and their more quiet brethren do not know how to stop them.

ASTIGMATISM; ITS RELATIVE IMPORTANCE IN ASTHENOPIA DUE TO ERRORS OF REFRACTION.

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

A long and painstaking experience in correcting errors of refraction, for the purpose of relieving asthenopia, will finally show that the difficulties in accomplishing the best results possible are not as great as they seemed to be in the infancy of our knowledge of the subject. I say infancy deliberately, because it was not until 1861 or 1862 that any accurate work of this kind, based on the investigations of Donders, of 1859, was done in the United States, and then only in the great cities and to a limited extent.

It was not until 1861, or thereabouts, that there was any exact knowledge of general accord in the profession on the matter of the prescription of glasses. This was when astigmatism and hypermetropia began to be understood. As an illustration of what I am saying, I may refer to an article upon astigmatism by the late Freeman J. Bumstead in the *American Medical Times*.[1] That such an elementary article was needed at that time shows how far we have now come in the progress of knowledge upon this subject, and what an infancy we were then passing through. It is interesting to note that Dr. Bumstead states in his article, which was founded upon a single case of myopic astigmatism, that "cylindrical glasses cannot at present be made in this country, at least in New York."

In these thirty years the profession in the United States has learned that asthenopia, when not dependent upon constitutional conditions, chiefly results from hypermetropia, hypermetropic astigmatism, or mixed astigmatism. Fitting glasses for myopia and presbyopia is comparatively simple work, and the rules for it are not very much in dispute. Those who come to the oculist with these conditions are not usually asthenopic, but simply require glasses, in order that they may see more distinctly, either at a distance or near at hand.

When we come into the field of asthenopia of young people, which is usually based upon hypermetropia or hypermetropic astigmatism, we are on ground which, although often fought over, cannot be said to be in the full possession of any one of the parties that claim the right to it. A more complete understanding and agreement as to the proper mode of procedure in these cases of asthenopia, and chiefly by the use of the ophthalmometer, is being reached. It is easy by its use to exactly measure the corneal astigmatism in every case. We can, therefore, I believe, dispense with any mydriatic for the purpose of suspending the accommodation, except in very rare and entirely exceptional cases. We have only to subtract one-half a diopter, as Javal has taught us, from hypermetropic astigmatism, "with the rule," that is, the vertical meridian being the one of greatest refraction, and to correct the full degree of astigmatism of that "against the rule," to be able to know in a large proportion of cases just what glasses are adapted to the patient, independent of his or her answers.

Retinoscopy, now greatly lauded where the use of the ophthalmometer is not thoroughly known, also is far behind the exact, because objective determinations of this instrument. Retinoscopy may be entirely dispensed with in determining astigmatism.

This is a great advance. But I believe, working on the same lines, that we can go a step further in the asthenopia of young persons, and that is, we may disregard the hypermetropia that almost always exists, and prescribe only cylindric without spherical glasses. That is to say, it is sufficient to correct the astigmatism which we find by the ophthalmometer. If the patient is not presbyopic, he will himself comfortably overcome the hypermetropia, until presbyopia has occurred; when it will be no longer possible, and the glasses will be stronger in proportion to the degree of hypermetropia. Hypermetropia may be said to be the refraction of the normal eye, as has been claimed in a recent number of this Journal by Dr. Van Fleet, and has been previously more than intimated by myself and others.

I believe it is high time that the whole subject of normal or usual refraction of the human eye was rewritten. Donder's work was only the beginning—a correct and epoch-making beginning, it is true—but with the imperfections of a beginning in the elucidation of a science which is still very young.

I cannot undertake to say, from my three years' experience in correcting hypermetropic astigmatism by the ophthalmometer, that we can lay down a positive rule as to what degrees of hypermetropia may be disregarded in the case of young subjects, while the astigmatism alone is corrected, but I am inclined to think that as high as two and a half diopters may thus be treated, and possibly, sometimes more. A large number of observations, continued for a long time, may be necessary to show those not now using this instrument the great advantage in the use of the ophthalmometer over the other methods of determining, and consequently of correcting the refraction, especially in those cases of which I am now writing. Perhaps we may lay it down as a rule that spherical glasses need not be prescribed when the vision is not improved by spherical glasses, or even in facultative hypermetropia, when the vision is the same with or without spherical glasses. This leaves a relatively small number of those who consult us in regard to asthenopia to be fitted with spherical glasses. As is generally known, myopes are not usually asthenopic, although myopia has many dangers, nor are presbyopes. Those who have asthenopia are in large proportion young persons, or relatively so, that is, under thirty-five years of age, and they usually are hypermetropic. In the term asthenopia I include headaches beginning in the eyes or directly referred to their use, and which usually cease when the eyes are not used in fine print, or sewing, or similar occupations. Very few people who have no positive ocular symptoms, but who because they have neurotic symptoms think their trouble may have its origin in the eyes, come to me. Those who do so are usually sent by a neurologist. I do not often find that such patients secure much lessening of their general symptoms from the prescription of glasses, although uterine patients do in large proportion. As I have had occasion to say in other papers, if irritation be reflected from an organ there will usually be irritation in the organ itself. Wax in the ear that causes epilepsy will also produce impairment of hearing and tinnitus. A foreign body in the eye that causes sympathetic irritation will also cause serious consequences at

[1] Vol. vii., p. 203, October 31, 1863.

its point of entrance or somewhere in the globe; a diseased tooth that causes failure of accommodation or keratitis will have a tender gum.

I do not believe that the eyes are a source of disease when no organic lesion can be discovered in them, or when no congestion exists in them, or no asthenopia results from their use. There has been very little added to what Donders wrote in the treatises and papers that is both true and new, except in the writings that are based upon the conclusions of the ophthalmometer. Many writers have rung changes upon the old tunes, but until we had an objective means of measuring astigmatism even Donders's errors remained uncorrected, while the subject upon which he appears to have no very positive ideas, that is, the insufficiencies of the muscles, have been greatly expanded in the line of Graefe's investigations, as well as those of Loring and others upon the insufficiencies of the interni, and the old French errors of muscular asthenopia have been revived and expanded, especially in this country.[1]

It was formerly the habit of most of the oculists, with whose work I am familiar, to correct a certain proportion of the hypermetropia, and if astigmatism existed, to correct nearly the whole of this. This was my own plan. My conviction is that a correction of the astigmatism will usually be sufficient. If this be so, it will be readily seen that we can get on without the mydriatic, which is an incidental point that I am endeavoring to make. It is not to be denied that the method just mentioned, of correcting both a part of the hypermetropia and all of the astigmatism, produced good results in a majority of cases, but I am inclined to think that the simpler and easier plan of correcting only the astigmatism is even better, and that it succeeds in some cases when the other failed.

Those who are familiar with my views upon asthenopia well know that I do not believe that it is possible to relieve every case of asthenopia, even in young people, or in those who are not presbyopic, by glasses. Nervous exhaustion in one form or another—and it has many—comes in to prevent this, and many are finally relieved not by glasses but by hygiene, and so sometimes by drugs.

But the correction of errors of refraction must be newly studied in the light of the perfection of the ophthalmometer by Javal and Schiötz, and in that of the rapidly accumulating evidence that the hypermetropic eye is the normal one, and astigmatism also is a widely prevalent condition, which if not of so high a degree as to impair vision, even to a greater degree than was formerly supposed, produces no harm, no asthenopia. It is not too much to say that these advances in our knowledge will produce finally a revolution in the science and art of the correction of errors of refraction. It is amazing that the change is not already more widespread.

In Germany it may have been retarded by prejudice, but that cannot obtain in our country. The following cases illustrate to some extent what has been said in the preceding paragraphs. They are appended to make them more fairly understood, and not with any idea that they embody the whole of the final truth on these subjects.

Case I. *A Neurotic Person, with Headaches, gets Relief from the Correction of Astigmatism only.*—Mr. W——, aged thirty. This patient was sent to me by Dr. C. L. Dana, who wished his eyes examined, not that Dr. Dana supposed that all his symptoms were caused by his eyes. He said that he had been subject to headaches for the last ten years; there is constant pain in his forehead, vertex, and occiput, and at times a sharp pain starting from the right eye and extending over the right side of the head to the back of the neck. He does not think his eyes cause his headache, but his eyes pain him when he uses them. His general health is good. He is wearing glasses of + 0.50 D. spherical. He has a sister and brother who were relieved of headaches by using glasses for astigmatism. His vision is $\frac{20}{30}$ in each eye; becomes $\frac{20}{15}$ by using a glass of + 0.50 D. + 0.50 c. 90°. The ophthalmometer shows him to have only 0.75 D. with the rule, on the right side, and 1.25 on the left. He was ordered a + 0.50 c. 90° for the right eye, and for the left + 0.75 c. 90°. Two weeks afterward the patient came in to say that he did not have so many headaches, did not frown, glasses seemed to be a rest to him, liked them very much, and four weeks later he said the same. This patient has considerable hypermetropia, besides the astigmatism. It is my belief that such cases of astigmatism are usually much benefited by cylindrical lenses, although these headaches do not entirely disappear. Less neurotic persons will sometimes tolerate as high a degree of astigmatism without headaches and without asthenopia. This is what I should call a mixed case.

Case II. *A Clerk, who has always had Headaches at Intervals, finds Ocular Relief from the Correction of Astigmatism.*—Henry J. S——, nineteen years of age. A clerk by occupation. He states that he has been subject to headaches all his life, his eyes pain him on use, blurring at times. His general health is good. His headaches are in his eyes and run up to his head; he sometimes wakes up with them, but he gets worse on use of his eyes His vision in the right eye is $\frac{20}{20}$—becomes $\frac{20}{15}$ by using + 0.50 c. 90°, same result on the left side. At some moments he declines all glasses on the left side. This is one of the eyes in which the cornea moves under the instrument, and it is very difficult to measure with the ophthalmometer, but we discovered at least that he had 1 D. with the rule at 65°, that is, 25° off from the vertical in the right eye, and 1 D. with the rule at 90° in the left. He had 1.50 D. of hypermetropia, and was ordered + 0.50 D. + 0.50 c. 65° in the right, and + 0.50 c. 90° in the left. Fourteen days after he writes: "I find the glasses you prescribed for me have been a great help; have had no headaches since, and my eyes feel very much rested after a day's work." Nothing has been heard from him since.

Case III. *Nervous Exhaustiona Cause of Asthenopia; very low Degree of Astigmatism; Relief only by giving up Use of his Eyes.*—The patient was sent to me by Dr. George T. Elliot. He is a student at Yale College, and had worked very hard to get into college. He entered without conditions, but, after getting in, finds he has so much pain in his eyes and head on use, and so much blurring, and so much general debility and indisposition to work, that he wishes to know what can be done for his eyes. He lived a very sedentary life before going into college. His vision is $\frac{20}{20}$ + in each eye. By the ophthalmometer he has 0.75 D. with the rule in the right eye, and 0.50 D. in the left; considerable hypermetropia, say two diopters. I expressed the opinion that his was a case in which the asthenopia was only a small part of the general condition, and I prescribed that he leave college and devote himself to an out-of-door life for a year, when I hope he may return without being oppressed by the use of glasses. If he had had a diopter and a half of corneal astigmatism, instead of the low degree which he did have, I would have expected a little more from glasses.

Case IV. *A Lady in Good Health, nearly Forty, has Asthenopia in the Evening; gets Relief from the Correction of Astigmatism only.*—This lady complains of asthenopia in the evening. She is in fairly good health, not particularly robust. Her vision is $\frac{20}{20}$ + in each eye. She has 2 D. of astigmatism with the rule. Her general refraction is hypermetropia. She was ordered a + 0.75 c. 90° in

[1] In a recent paper by Dr. G. A. Berry, of Edinburgh, in the Transactions of the Ophthalmological Society of the United Kingdom, vol. xi., p 57, occurs a paragraph which is likely to disturb the equanimity of those who speak of us who disbelieve in muscular asthenopia as such a small minority:

"For my part, I regard the practice, which to judge from the literature of the subject is not uncommon in America, of frequently performing tenotomies, or so-called partial tenotomies for lateral deviations, as a disgrace to modern ophthalmology. As to the frequent ordering of prisms for similar conditions, that is a practice which, while it displays the same ignorance, is open to less serious objections, inasmuch as it only affects the pockets of the patient and that to a less extent than operative interference."

each eye for close work. She came six months later to see me, on account of another patient, and she told me that her asthenopia had been entirely relieved, that her glasses were perfectly comfortable. This is an interesting case, from the fact that the lady is nearly presbyopic, aged thirty-seven, and that she is able, without any correction of the general hypermetropia, to get on in perfect comfort with the correction of the astigmatism.

Case V. *Blepharitis and Asthenopia; Relief from Correction of Astigmatism.*—Mrs. D——, aged thirty-five. This patient suffers from asthenopia, and chronic blepharitis. She was found to have nearly normal vision, and accepted cylindrical glasses. On the right 1 D., on the left .50 D. Her refraction was hypermetropic. The ophthalmometer made the corneal astigmatism 1.50 D. on the right side, and 1 D. on the left. She was advised to wear + 0.75 c. 90° and + 0.50 c. 90° on the left for close work, with no correction of the hypermetropia, and two months after she reported that her glasses were perfectly comfortable.

Case VI. *Headaches and Double Vision; Correction of Astigmatism only; Relief.*—Miss A. D——, aged twenty-eight. This patient has had many headaches, for which she has worn + .50 D. and + .50 c. 90°. At times she sees double. Her vision is $\frac{20}{30}$ —. By the ophthalmometer she has 1 D. of astigmatism in each eye, with + .50 c. 90°. Her vision becomes $\frac{20}{20}$ —. She had three diopters of hypermetropia in each eye, but this was totally disregarded; + .50 c. 90° ordered for each eye, and six weeks after she wrote that her glasses were comfortable, and that the headaches were less frequent. This again was a neurotic case in which the astigmatism became the last pound to break the camel's back.

Case VII. *Double Vision; Headaches; Relief by Correction of Myopia and Astigmatism.*—Maria C——, aged eleven. This young girl complained of headache and of seeing double. Her vision is only $\frac{20}{100}$ in each eye. By the ophthalmometer she has 3 D. of astigmatism with the rule. The prominent feature in this case is the marked insufficiency of the interni, and the occasional double vision. Her refraction was myopic. She was ordered a —1 D. in the right eye, added to a —1.75 c. 180, and in the left a —5 D., added to a —1.50 c. 180, with which her vision became $\frac{20}{30}$ in the right eye, and $\frac{20}{40}$ in the left. She was seen one year after, when she stated that she was much more comfortable, very much improved, never sees double, but her eyes "get twisted sometimes, but they soon get untwisted." The concave sphericals were increased, but the cylindricals remained the same. This case illustrates the fact that positive double vision may be entirely relieved by the correction of the astigmatism. I have never asserted that prisms may not in some cases do the same thing, but with a correction of the refraction, muscular insufficiencies are fundamentally cured, not merely assisted by crutches.

Case VIII. *Double Vision; Migraine; Partial Relief from Correction of Astigmatism.*—This patient has been subject to headaches since she was a girl. The eyes do not pain her, but she has "some doubling of vision" when she has the headache. Sees objects double. There was no double vision when she visited my office. The pain was chiefly over the orbit, and then in the back part of the eye. The diagnosis, by Dr. Graeme Hammond, who sent her to me, was migraine. Patient said this could be easily induced by anything requiring constant use of the eyes. Except being anæmic, patient was well. Her eyes had been put under the influence of atropine before she came to the office. With the ophthalmometer, on the right side, she was found to have 1 D. of astigmatism with the rule, the axis being from 30 to 35° from 90°. In the left eye she had 1 D. with the rule. She was advised to wear, for close work, on the right side, + 0.50 D. + 0.50 D. c. 45°, and on the left, + 0.50 D. c. 90°. Her vision was $\frac{20}{30}$ in the right eye, and $\frac{20}{40}$ in the left, with these glasses. These glasses proved to be perfectly comfortable. Six months later, the patient stated that she could read all the evening, but she could not sew, and she had an occasional sick headache, but not so many as formerly. She liked her glasses very much, and was disposed to wear them all the time, to prevent what she calls dizziness and double vision. The patient is still anæmic and neurotic. I think this she will always be, but the glasses are great palliatives.

Case IX.—The following case illustrates the interesting observation that correction of the astigmatism is sufficient, where there is a very slight degree of astigmatism against the rule, and considerable hypermetropia.

Mrs. A——, aged thirty-six. This lady has had trouble with her eyelids for five or six years. Has blepharitis ciliaris; no asthenopia. What I observed in 1878, in my first paper on the relations of blepharitis ciliaris to errors of refraction, was markedly true here in regard to the absence of asthenopia. Patient's vision was $\frac{20}{20}$—. With the ophthalmometer she had 0.25 D. astigmatism against the rule. On some examinations with the ophthalmometer she seemed to have no astigmatism, but we finally concluded that there was separation of the mires, to the extent of 0.25 D. in the second position. She was ordered + 50 c. D. 180 in each eye. Three months later, the patient writes that she has had no trouble since using the glasses.

Case X. *Asthenopia; Relief from Correction of Astigmatism alone.*—Susie L——, aged sixteen. November 14, 1891. The patient's eyes smart, burn, and pain on use; occasional headaches. The trouble has existed but a very short time. Is using her eyes eight hours a day, sometimes ten hours. Her vision is $\frac{20}{20}$+ in each eye. She has 1 D. of astigmatism, and her eyes are hypermetropic. She was ordered a + 0.50 c. D., 90°, and three weeks later she writes me: "My eyes are not at all painful, and are much improved from using the glasses."

Case XI. *A Case in which Correction of the Hypermetropia and Astigmatism was not as Beneficial as Correction of the Astigmatism only.*—An insurance underwriter, aged twenty-seven, uses his eyes all day; has had trouble with them since he was twelve years of age; watering, tired feeling, etc. Began to wear glasses in 1886. Has had excellent advice, but has always worn spherical as well as cylindrical glasses. He has 0.50 D. of astigmatism against the rule. He has 1 D. of hypermetropia by the ophthalmoscope. Judging from the records of competent men which he brought with him, he had much more under atropine, for he was wearing as much as + 4 D. sphericals added to his cylindrics. He was ordered + 1 c. D., 180° for the right eye, + 0.75 c. D., 180°, for the left eye. On December 22, he writes: "The glasses you prescribed for me have not only relieved me from all the headaches I have had so long, but have been as a new pair of eyes to me.

This case illustrates in a marked way the general theme of my paper, that is, that the astigmatism is the chief factor in producing asthenopia. This patient has had more comfort under correction of the astigmatism alone than when the hypermetropia was also corrected. But as I have already said, we must always regard a considerable degree of hypermetropia as a normal condition; and as I shall show in a subsequent paper, astigmatism even by itself, although more disturbing, as a rule, than hypermetropia, requires, so to speak, a certain setting, in general neurotic conditions, in over-use of the eyes, nervous exhaustion, the coming on of presbyopia, and other concurrent factors, before even it will produce asthenopia. The almost complete uselessness of paralyzing the accommodation, when we can now accurately and quickly determine the corneal astigmatism by the ophthalmometer, is also incidentally shown.

A Health Treaty between the United States and Mexico, "for the reciprocal protection of both countries against infectious diseases of men and animals," has been suggested by the Board of Health of the City of Mexico.

THE CAUSATION AND TREATMENT OF CHRONIC DIARRHŒA.[1]

By W. W. VAN VALZAH, A.M., M.D.,

NEW YORK,

FORMERLY DEMONSTRATOR OF CLINICAL MEDICINE, JEFFERSON MEDICAL COLLEGE.

It is not always possible to connect chronic diarrhœa with a distinct lesion of the intestine, nor can we limit its origin to functional or organic defect of the digestive system. It is by no means rare to find it one of the symptoms of disease of a distant organ, or disorder of nutrition, or defect of elimination. But chronic diarrhœa is a symptom so frequent that it may serve as a convenient point from which to begin investigation so important as to often command our whole attention, and so predominant as to dictate the treatment. Whenever present it stands out in bold relief in the clinical picture, and necessitates a search for its hidden meaning. The term "chronic diarrhœa" may be made to serve a useful clinical purpose, and no apology need be offered for selecting it as the subject of a paper based on investigations at the bedside.

Fluidity is the most constant characteristic of the diarrhœal stool. This physical quality results from excessive secretion, or transudation, or increased peristalsis and diminished absorption. The stools are also altered chemically and microscopically, but the character of the discharges varies very much with the age, diet, the nature, and location of the disturbance. The frequency of the evacuations is also no criterion, and varies widely both in health and in disease. But habit and other influences establish a certain routine which, though it varies with each individual, may be taken as a standard. The character and frequency of the stools will nearly always enable us to make out the presence of the symptom. Moreover, diarrhœa, whether conservative or not, is always an exhausting process, and when long continued must inevitably affect the general health. Hence, chronic diarrhœa may be defined as the frequent evacuation of the fluid, and usually abnormal, contents of the intestine, with more or less impairment of the general health.

A classification of chronic diarrhœa based on the changes in the stools is not desirable. A careful study of the stools will not fail to yield some useful information. But in the same case the character of the stools varies from day to day, and bears no definite relation to the lesions.

A classification based on etiology would be more scientific, and stands in direct relation to the advanced treatment which strives to go beneath the surface and strikes at causation. A careful review of the possible causes will aid very much in formulating a rational treatment, but our knowledge at present is too incomplete to enable us to make a scientific etiological classification.

A nomenclature based on pathological findings is neither desirable nor practical. Morbid anatomy is only a symptom of unhealthy cell activity, and widely different processes find expression in the same tissue changes. But the lesions must be taken into consideration in formulating the treatment.

In studying a case of chronic diarrhœa, I constantly keep before me two objects of commanding importance: the detection of the proximate and remote causes, and the discovery of the nature and location of the intestinal lesion. In this way we gain all the information that is of most value in the management of the case.

The proximate cause of every diarrhœa is located in the intestinal wall. The intestine is a secreting, absorbing, and eliminating tube, which propels its contents in a peculiar way, and in which the most important part of digestion takes place. In diarrhœa, too much fluid is poured out from the mucous membrane, or too little fluid is absorbed, or the contents of the intestine are hurried along too rapidly. It is common to find two, or even all, of these factors active in a particular case.

[1] Read before the Medical Section of the New York Academy of Medicine, February 16, 1892.

Diarrhœa from supersecretion is a frequent variety. It is commonly due to local irritation, with here and there patches of catarrhal inflammation. It is also found in chronic nerve or blood states, and may often be traced to auto-infection as the remote cause. Chronic dyspeptic diarrhœa may be taken as the type of this form. Much mucus, and a disproportionate quantity of undigested food, especially starch, are found in the stools.

The excess of fluid may be an exudate, as in a condition of the mucous membrane analogous to an eczema or herpes. Or the fluid may be transuded in passive congestion, such as occurs in hepatic cirrhosis, obstructive disease of the lungs, or uncompensated valvular disease of the heart. The pathognomonic sign of this variety is the presence of serum-albumin in the stools.

The intestinal mucous membrane is also an eliminating organ, and diarrhœa is not rarely due to exaggeration of this function. The diarrhœa of chronic Bright's disease and septicæmia are types of this form.

Diminished absorption may be the starting-point of a diarrhœa. But a diarrhœa originating in this way will not long remain simple, as the resulting superdigestion, fermentation, and putrefaction will produce supersecretion, exudation, and excessive peristalsis. Impaired absorption always forms one of the links in the etiological chain, and has as much to do with the persistence as with the causation of diarrhœa. The stools contain completely digested products.

Diarrhœa from excessive peristalsis is neuro-muscular in origin, and occurs in its simplest form in neurotics with lively reflexes or with hyperæsthetic mucous membranes. Exaggerated peristalsis, however, usually results from a local irritant. A stool occurs regularly and rapidly after each meal, and consists chiefly of unaltered food.

From this it will appear that diarrhœa is wholly or in part a conservative process in every variety, except that which is purely nervous in origin, and this variety, it must be admitted, is but rarely met with.

These divisions are based on unhealthy variations in the physiological processes—the surface play of concealed forces. While it will not clearly reveal the manner of appearance of the diarrhœa will suggest the salient features of the underlying disturbance. The kind of fruit or flower will enable us to infer something of the nature of the seed, and the development of the plant. It is always difficult, and sometimes impossible, to discover the remote cause, be it located in a disorder of nutrition or hidden in the disease of a distant organ.

Disease of the kidneys, heart, liver, lungs, and spleen must usually be well marked in order to produce a diarrhœa. Anæmia, gout, leukæmia, Hodgkin's disease, scurvy, syphilis, tuberculosis, and septicæmia must also be passed in review and excluded.

A very large percentage of all cases of chronic diarrhœa find their origin in derangement of one of the three great processes of nutrition—digestion, absorption, and metabolism. The perfection of each one is essential to the integrity of the whole, this constitutes the solidarity of the nutritive processes. From a therapeutic stand-point, it is of great utility to locate the primary disturbance. The presence in the urine of the incompletely elaborated products of tissue waste, such as uric acid and the urates in excess, and of pathological urobilin, would point to faulty katabolism; peptones, albumin, or sugar in the urine might implicate assimilation; while the discovery in the stools of the digestive products in a fluid and diffusible form would suggest defective absorption. But the nutritive disorder more often takes it origin in the digestive tube, either in gastric dyspepsia or inflammation, with alteration either in the chemical process or in the muscular movements; or in intestinal indigestion from faulty chyme, bile, pancreatic secretion, or intestinal peristalsis. An insufficient diet, of which simple emaciation will be the evidence; unhealthy food, and impure drinking water, an improperly constitued diet, will often be found the ini-

tiating causes, though secretion and muscular movement be in every way normal.

An important connecting link in the causation of chronic diarrhœa is auto-infection, which may be from the digestive or from the general system. Absorption of the products of superdigestion, fermentation, and putrefaction is one source; defects of assimilation and disassimilation, increased cell activity and tissue waste, and incomplete elimination are others. The quantity of toxines formed in health may be increased, or new ones may be manufactured in defective nutrition, or bacterial products be absorbed, and self-poisoning will result unless elimination is very rapid. Some of the toxines dilate and others contract the blood-vessels, some alter the blood as well as the blood-pressure, thus impairing secretion or causing exudative or productive inflammation. Some paralyze, others excite, the nerves; all exercise a pernicious influence on nutrition. The prevention and treatment of auto-infection is the most important part of the management of chronic diarrhœa.

It has been ably maintained that we never have a diarrhœa without the presence of an enteritis. But it is now a fact pretty well established by careful autopsies that diarrhœa frequently is not accompanied by noticeable lesions of the intestine. From a practical point of view the detection of the cause is of much greater utility than the diagnosis and location of the lesion. The chief advantage of a knowledge of the anatomical state of the mucous membrane is the light it throws on prognosis. But the nature and location of the lesion afford certain indications in treatment.

I have been in the habit of grouping all my cases into two large classes, according as there is or is not a marked lesion of the intestine, and try to decide whether or not ulceration is present. This classification is somewhat arbitrary, but it is usually possible to group the cases on this wide basis. Our stand-point is at the bedside, and this broad classification, in which minute anatomical distinctions are not made, has a practical bearing.

In the functional disorder the symptoms are milder and may be intermittent, there are no persistent points of tenderness and no thickening of the bowel, and the stools contain no products of inflammation.

A large number of chronic cases with intestinal lesions follow acute attacks that have their remote cause in the digestive system, or form part of the clinical history of the acute infectious diseases. The persistence of pain, tenderness, and fever would indicate the presence of an important lesion. The discovery in the stools of much epithelium, mucus, and unaltered bile-pigment, of pus, blood, false membrane, and pieces of tissue from the intestinal wall, would prove the trouble to be organic. Chronic gastritis with chronic diarrhœa is accompanied by chronic enteritis.

Ulceration of the intestine is simple, syphilitic, tubercular, or malignant. The signs of a lesion, in many cases the strict localization and persistence of a painful and tender point, the presence and continuance of much pus, blood, and mucus, without tenesmus and the detection of bowel tissue in the stools, establish the diagnosis of ulceration. Intestinal carcinoma is usually located in the rectum, and can commonly be felt by the finger through the anus; cachexia and rapid decline will also point to malignancy. Simple ulceration results from a severe catarrh, or from acute or chronic follicular inflammation, and commonly involves a large extent of surface. Syphilitic and tubercular ulceration is more strictly localized, and the disturbance of the digestive process above the lesion is from excessive peristalsis. In syphilis we may get a specific history or characteristic skin lesion, or a persistent headache with periodical exacerbations, and attended by insomnia and unwonted irritability of temper, an early endarteritis, or other sign of this protean malady. Tubercular ulceration is almost never found apart from pulmonary tuberculosis, and the rapid pulse, dry skin, hectic fever, and localized physical signs will confirm the suspicion. The absolutely pathognomonic sign is the discovery of the tubercle bacillus in a shred of the bowel tissue found in the stools.

The character of the stools, the persistent points of tenderness, and other physical signs, taken along with the clinical history, will locate the lesion with a good deal of exactness. The lower the lesion, the more frequent and more painful are the movements. It is rare to find the small bowel alone diseased. The large bowel is nearly always involved, commonly associated with it is disease of the lower ileum. It is near the ileo-cæcal valve that bacteria abound, that fermentation and putrefaction are most active, that irritants long remain in contact with the mucous membrane. When either the small intestine or the colon is alone diseased, there will be periodical attacks of diarrhœa; when both are involved the diarrhœa is likely to be continuous. Pain occurring just before a movement is usually located in the colon. Tenesmus is present only in proctitis. Indicanuria, fatty stools, recurring slight icterus, and persistent flatulency in the small intestine, are pathognomonic of duodenal defect. Much unaltered bile-pigment and mucus intimately mixed with the fæces point to the small intestine. When the trouble is located in the ascending colon the stools are soft, muco-feculent, and little yellow globules of mucus are visible; and hard fecal lumps coated with mucus from the lower half of the large gut. When from the rectum, the stools consist of yellowish or blood-stained white-of-egg mucus, or mucus and fibrin shreds; and the lower colon and rectum may furnish a shred or cylinder, formed of a net-work of fibrin filled with mucus, with here and there an epithelial cell on the surface, or exfoliated casts of false membrane.

Having briefly reviewed such points in etiology, differential diagnosis, and localization as can be utilized at the bedside, turn we now to the treatment.

Good hygienic surroundings, a regulated life, and a proper diet will often suffice to cure a mild diarrhœa. But the severe cases must be subjected to a rigid régime. Many of these patients have tried everything, done nothing thoroughly, and lost faith and hope. An important strategic point is already gained if we win the confidence and arouse so strong a desire to get well as to cause every energy to be bent in the direction that we dictate. The successful management of these cases depends as much on the co-operation of the patient and the detailed observance of directions as on the skill of the physician. It is not enough to order, but instructions must be carefully and cheerfully obeyed. Of so great importance are co-operation and attention to detail, that I no longer try to cure these patients against their expectation and will. They must acquire a soul forwardness toward health—every thought, feeling, and emotion must be enlisted in the work.

Having secured the confidence and hearty co-operation of the patient, we give minute directions as to clothing, bathing, rest, and exercise. From malnutrition and auto-infection the vaso motor centres are weak and irritable, and paling of the surface leads to a corresponding internal congestion. Hence the necessity of warm clothing, especially over the abdomen, to protect against sudden changes or extremes of temperature and loss of body heat. The rapidity and completeness of reaction guide in the selection and the mode of bathing. In the beginning, a warm plunge or sponge bath in a warm room should be advised, and the difference between the temperature of the air and the water cautiously increased from day to day. The bath improves the function and nutrition of the skin and tones the nervous system. It has been demonstrated that the toxicity of the urine is increased during the administration of the Brandt treatment of typhoid fever, and the increased elimination of toxines is not the least of the benefits derived from bathing. If the stools are frequent and exhausting, absolute rest in bed must be enjoined; during convalescence moderate exercise and fresh air will hasten the cure.

Over-fatigue, mental and physical, must be scrupulously avoided, temperance and moderation being the guides of conduct. The mode of life must be put on a physiological basis, and as much energy and vitality conserved as possible.

The curative treatment of a chronic diarrhœal disease has very little to do with the control of the symptom by the use of opiates and astringents; we must go behind the lesion of the mucous membrane and strike boldly at causation. Behind the veil are the hidden forces at work, beneath the surface are the sources of evil. It is a waste of time to strike at the shadow; it is useless to close the volcano's mouth while the subterranean fires are still burning. The curative treatment of a chronic diarrhœa must be etiological.

Active elimination by all of the emunctories is also a sheet-anchor in the treatment of chronic diarrhœa. Free drainage is the first law of surgery, and free drainage is a controlling principle in the treatment of a chronic disease accompanied by or resulting from auto-infection. We have already seen that a chronic diarrhœa is largely a conservative process, and is just as essential as the drainage of a septic wound. Checking a chronic diarrhœa by astringents and drugs that paralyze muscular movement before the digestive tube is made clean and sweet, can only produce a violent explosion which will widen old rents, or find new points of exit where resistance is weakest. So great is the danger of auto-infection from the alimentary canal that nature has well barricaded the system against invasion from this quarter. An active peristalsis to divert the enemy, mesenteric glands and the liver to arrest and destroy, oxidation to burn, the skin, kidneys, and liver to turn aside or sweep away—these are the strong barriers which our treatment must support and strengthen. Impaired digestion, defective absorption, mal-assimilation, auto-infection, are heavy blows against nutrition. To build up the blood so that it may perform its work is a controlling object. Healthy nutrition is a hope that only careful alimentation can realize. These are the important general considerations: on the one hand, the bright side of the shield, a well-fitting armor, a determination to conquer, and on the other, the removal of the cause, careful alimentation, and active elimination.

Of no less importance are the local indications: 1. To cleanse the alimentary canal and keep its contents sweet. 2. To secure perfect digestion of the food taken. 3. To promote absorption. 4. To diminish the work of the diseased part. 5. To treat the lesions. 6. To treat the sequelæ. 7. To control the harmful symptoms.

Our first object is to cleanse the alimentary canal, and cholagogues and purgatives will render efficient service in its accomplishment. An increased flow of healthy bile will meet more than one indication—it is not irritating, is laxative, and also aids in digestion, absorption, and the prevention of decomposition. Podophyllin, ipecac, salicylate of sodium (or better, salacin and bicarbonate of soda), and the bichloride and biniodide of mercury are the most useful cholagogues. To get their selective action on the liver these drugs should be given in minute doses. Small doses of calomel also act well, especially if the kidneys are sound, or the heart diseased, or arterial tension is high, or the bile-ducts distended. Cascara sagrada is the most valuable laxative—it increases peristalsis by its action on the nerve-supply of the intestine, washes out the glands and follicles by augmenting their secretion, and in laxative doses is unirritating, an important negative quality that often secures for it preference. Those drugs should be selected which least irritate the diseased part; too much care cannot be exercised in this respect, as these remedies cut both ways, and can do harm as well as good. Stomach washing will also help us to clean a part of the alimentary canal. When this important viscus is dilated and incapable of emptying itself completely, when the muscular movement s defective, and the food is fermenting, decomposing, or undergoing superdigestion, the procedure is a valuable one, but must not be repeated too frequently. But when not dilated, and strong enough to empty itself, the stomach can be efficiently and agreeably washed out by copious draughts of hot water. Hot water is also a powerful hepatic stimulant, liquefies the bile and washes out the liver, which is often infected from a septic duodenum, or through the portal vein or hepatic artery. The liver is the great central depot for the arrest, destruction, and elimination of toxic material, and the entero-hepatic circulation should be frequently flushed out. Hot water does this very rapidly and efficiently. The large bowel is the seat *par excellence* of fermentation and putrefaction, and the most frequent source of auto-infection. It can be thoroughly washed out with warm or cold water, to which an alkali should be added if there be much mucus in the stools. The use of antifermentatives and antiseptics is rendered necessary by the inefficiency of lavements, cholagogues, and laxatives to accomplish our purpose—the cleansing of the digestive tube. I only use a few of the drugs of this class, the ones that I have found the most efficient—salicin, the biniodide of mercury, salol, and the subnitrate of bismuth. Salicin is the best sweetener of the stomach, given in ten- to twenty-grain doses, two hours after meals, or one hour before breakfast and retiring. The biniodide of mercury is valuable in small doses when the decomposition is in the small bowel, chiefly on account of its action on the liver. Salol is by far the best duodenal antiseptic. These three drugs act locally, and also by exciting a free flow of the natural intestinal antiseptic—healthy bile. Cholagogues spur onward the entero-hepatic circulation, as Rosenthal has shown that both bile and the biliary salts are hepatic stimulants. Calomel is also an antiseptic, and some aid is derived from its passage along the intestine. Subnitrate of bismuth reaches the large bowel, but is not of much value unless given in very large doses. These drugs are very useful in combating putridity and maintaining the sweetness of the alimentary canal. It has been suggested that bacteria have something to do with digestion; I gravely suspect that enough will be left for this purpose after we have exhausted our means in the efforts to exterminate them.

It is also important to administer clean and sweet food and pure drinking-water. This is a matter of more moment than the little attention we bestow upon it would seem to indicate. How rapidly a septic colitis subsides when an impure drinking-water is withdrawn. How great a change is sometimes wrought by forbidding a food that is too "high" or has not been scientifically prepared. Attention to little details like these sometimes changes the whole course of the disease.

Having secured as nearly as we can a clean and sweet state of the digestive tube, our next object is to get perfect digestion of the food taken. This is an aim second to no other in importance. Undigested food in the wrong part of the intestine is an irritant. Rapid absorption is the chief barrier against superdigestion, fermentation, and putrefaction, and perfect digestion is the essential preliminary to the easy and healthy performance of this function of the mucous membrane. We attempt to realize this high aim by a proper diet, and by increasing or supplementing whatever digestive juice we have reason to suspect is defective. If the stomach is at fault in its chemical work we keep our eye on the acidity of the secretion, for the HCl is an important and the most frequently varying constituent of the gastric juice. The dilute HCl should be given in two or three doses of five or ten drops each, within two hours following the meal, and a small quantity of fresh pepsin may be added I suspect that a dose of toxines is often given in the name of this ferment. In the meantime we give such drugs as are known to increase or diminish the acidity of the gastric juice. If the liver or pancreas be at fault, we use the drugs that have a selective action on these glands, and supplement with fresh bile and pancreatin by the mouth.

It is best to precede their administration by an alkali. The time of giving them is two and a half or three hours after meals, except on the milk diet, when the proper time is just before each feeding. Duodenal digestion is thus made to begin in the stomach. If the muscular movements of the stomach and intestines are defective, strychnia, massage, and electricity will render important aid. Diarrhœa not infrequently has its cause in localized defective peristalsis—the contents collecting in the weak and dilated parts and undergoing putrefaction, fermentation, and hardening. With a clean digestive tube the secretions and movements of which have been regulated and supplemented, it remains to select a proper diet. This is the most difficult and most important part of the treatment. And here the physician should dismount from his "hobbies" and renounce so called "fads" and "cure-alls." Vegetarianism will rarely fail to do a good deal of harm—the milk diet in its many forms is not a panacea—a diet of animal food will not often fail to benfit, and has a very wide range of usefulness.

In selecting a diet we have a good many things to take into consideration. The evils of exclusiveness all are ready to admit. In any dietary the primary principles must be made to preserve a certain proportion in obedience to the laws of physiological chemistry, and such proportion arbitrarily altered to suit the needs and capabilities of general nutrition. But laboratory results need to be corrected and controlled by the testimony of the human digestive system. The diet habits of mankind and of the different nations of the earth furnish a rich store of information, for man, when permitted to do so, eats what most pleases the palate, keeps him well nourished and strong, and gives the least after-pain. Climate, age, activity, peculiarities, and the capability of the digestive organs are other important considerations. Now, in the diet of a chronic diarrhœa, the food must be chiefly digested by the stomach, contain the right proportion and proper quantity of proximate principles to meet the requirements of secretion, nutrition, and the production of animal heat, and leave no irritating or indigestible residue. Denutrition must be guarded against, and the diseased intestine given physiological rest and kept free from irritation. An exclusive diet of milk, or a diet of meat free from fibrous tissue would fulfil these indications—the one more completely than the other, perhaps—but both must be perfectly digested. Milk is a fluid, but becomes semi-solid during digestion. Meat is a solid, but becomes a fluid in its preparation for absorption. Milk may be a little more easily assimilated, but bulk for bulk is not so nutritious. The final product of the perfect digestion of the one is about as easily absorbed and unirritating as that of the other. Both require great care in selection, and the meat must be properly prepared and cooked. However, it is difficult to get day after day, milk which is free from pathogenic bacteria: it readily undergoes, both in and out of the stomach, chemical and bacterial changes with the formation of irritating and poisonous products; and I have found it well-nigh impossible to secure its continued perfect digestion during a period long enough for a cure to take place. When the gastric juice is hyperacid, or duodenal catarrh, or portal congestion, or fermentation are present, milk will not agree. The supreme test is the one at the bedside. In my experience a meat diet is much more valuable, less dangerous, and of a much wider range of application than milk in the treatment of chronic diarrhœa. Exclusive in the beginning, the meat must be supplemented by bread, cereals, and the more easily digested vegetables in the manner detailed by me in a paper on "The Management of Chronic Gastro-intestinal Catarrh," read before this Section, and published in the *New York Medical Journal*, March 23, 1889. It is the duty of the physician to see that whatever food be taken is completely digested and assimilated, and he has in the daily physical examination of the digestive system, and the analysis of the urine and the inspection of the stools as often as may be necessary (aided if needed by the microscope), a pretty sure guide. If the patient feels no pain, nor discomfort, nor drowsiness after meals, if there is no flatulency, if the urine contains no abnormal coloring matter, nor excess of phosphates, urates, or uric acid, and the stools contain no undigested products, we know that the food is being digested and assimilated, and, if there be no loss of strength, absorbed in sufficient quantity to meet the demands of life.

To avoid denutrition is not alone requisite: the barriers must be made strong; the body must be protected and defended, and built up. Not only a pure and adequate, but also a rich blood is needed. And the quality of the blood, its gain or loss of richness from day to day, can be detected by counting the corpuscles and measuring the hæmoglobin. No physician would now assume the management of a disease of the heart or lungs without the evidence and guidance of physical signs. No physician should now attempt to diagnosticate or treat a disease of nutrition without a study of the blood and excretions.

When we have an alimentary canal clean and sweet, and the lining washed free from mucus, containing a completely digested and unirritating fluid, much has already been done to promote absorption. An active enterohepatic circulation and the control of excessive peristalsis should complete the work. The relief of portal engorgement and the stimulating of the liver will aid the one, while the removal of local irritation and the quieting of the nerve endings and centres, and the strengthening of them by active elimination and improved nutrition have done much to realize the other. These are the curative means, but it is often necessary to control excessive peristalsis in order to keep the contents in contact with the mucous membrane long enough for absorption. Antacids, bismuth, and antispasmodics should be used instead of opium and narcotics. The control of flatulency also increases the absorptive surface.

The value of rest in the treatment of a disordered or inflamed part cannot be over-estimated. Repair is more complete, healing goes on more rapidly. An exudation in the process of organization is easily broken up by movement. Absolute rest of a diseased intestine cannot be attained without stopping drainage, but a great deal can be done by keeping the part free from irritants, and by the use of drugs that will lessen the exaggerated irritability, that will quiet the pathological unrest. The diet should also be selected so as to diminish the work of the diseased part. When the duodenum is the centre of disturbance (as it often is), the stomach must be made to do the work. When the disease is lower down, the diet must be such as is quickly digested and rapidly absorbed, and excessive peristalsis controlled. When the stomach and duodenum are able to do their work well, and the disease is in the colon only or low down in the ileum, a milk diet, if it agree, is superior to any other.

In the severe cases of chronic diarrhœa, when the muscular layer is atrophied or œdematous, or infiltrated with inflammatory products, constipation is very apt to supervene as soon as irritation is removed. I would like to emphasize this important clinical fact—that these weak points in the intestinal wall are often localized, and the obstruction in the drain must be overcome by massage, laxatives, and lavements. To clear out these depots of fermentation and putrefaction is an essential part of the treatment; until this is done there can be no rest, no healing.

The indications afforded by the lesions have been partly met by cleanliness, rest, and the prevention of irritation. If the lesion be syphilitic, specific treatment must not be neglected. When situated in the large bowel something may be accomplished by medicated lavements.

The treatment of the sequelæ resolves itself into the treatment of atrophy and deformity—the results of degeneration and destructive inflammation. A proper diet and a regulated life will aid nature in the readjustment

of the organism to the changed conditions. The deformity may demand the surgeon's skill.

The special and general treatment of chronic diarrhœa must often be modified or supplemented by the treatment of the causative disease.

In conclusion, the indications for the treatment of chronic diarrhœa may be thus briefly stated: 1. To remove or treat the cause, which presupposes its detection. 2. To improve nutrition and conserve energy. 3. To secure active elimination and prevent auto-infection. 4. To cleanse the alimentary canal and keep its contents sweet 5. To secure perfect digestion of the food taken. 6. To promote absorption. 7. To diminish the work of the diseased part. 8. To treat the lesions. 9. To treat the sequelæ. 10. To control the harmful symptoms.

A broad and comprehensive and etiological treatment, and one which I have found successful—a union of many powers which make for health, a union in which "all are needed by each one." It is not sufficient to meet the controlling indications, but regulations must descend into minute details. The moral management of the patient has a powerful and practical bearing. Two important elements of success are individualization and the persistent doggedness with which one enforces right living. The prescription of drugs is a very small part of the work which we have to do. The chief aim—the definite therapeutic purpose—is to secure healthy nutrition by careful alimentation, perfect digestion, and complete elimination, thus keeping in active circulation a pure and rich nutritive fluid. In no other way can we control and strengthen cell-life than by placing it in the best environment and obtaining the substitution of new protoplasm for that which is old and diseased. This is the basis of cure, the grand purpose which gives unity and system to the management.

10 East Forty-third Street.

THE COMPLICATIONS AND SEQUELÆ OF TUBERCULOUS LESIONS INVOLVING THE JOINTS, WITH A DISCUSSION ON THE MOST EFFICIENT MANAGEMENT.[1]

By V. P. GIBNEY, M.D.,

new york.

It is indeed difficult for one whose time is so fully occupied with the practice of a specialty, limited as is the one I represent, to prepare a paper which will afford scope for discussion in a Society whose name would indicate a membership of general practitioners. Fortunately, however, the Society has in its membership a small number only to whom the term "General Practitioner" is applicable. It was the aim of the founders of the organization to bring specialties together and have for discussion subjects in which all could participate. Armed with this knowledge, I do not suffer from a keen sense of embarrassment this evening when I present for your consideration

The Complications and Sequelæ of Tuberculous Lesions Involving the Joints.—Tuberculosis, we all know, has a medical as well as a surgical side. The bacillus against which such a ferocious war has been raised, is just as much at home in the epiphyses of bone as in the apex of the lung. When one speaks of chronic joint disease in children he naturally associates with this affection a tubercular pathology. When I speak of joint diseases I mean to convey the impression that the lesions are primarily tubercular. To be more specific—Pott's disease of the spine is a tubercular ostitis of the bodies of the vertebræ; hip joint disease is a tubercular ostitis of the upper epiphysis of the femur and the acetabulum; white swelling of the knee is a tubercular ostitis of the lower end of the femur and upper end of the tibia, and so on through the other joints.

I am well aware that a complication is often considered a part of the disease, and my only excuse for speaking of certain phases of the disease as complications is my desire to bring before you in a tangible way these very phases which often prove so embarrassing. The complications are few and may be named as follows: Tubercular meningitis, abscess, amyloid degeneration, compression myelitis. Among the sequelæ we have deformity, shortening of the limb, pulmonary diseases.

The two lists just given comprehend pretty much all the usual complications and sequelæ with which we have to deal. There are sometimes neuroses affecting the circulation, giving rise to purpura hæmorrhagica, sometimes a cystitis, permanent paralysis, etc. Yet these can scarcely be regarded as having any connection with joint disease.

Returning, now, to complications, I shall have very little to say about

Tubercular Meningitis.—This dread malady, in my experience, appears either in the first or second stage of joint disease and without exciting cause. I have seen it develop in mild cases where there are very little excitement; have seen it develop likewise at the close of an exacerbation, and sometimes within two or three weeks after an operation. I do not know that it occurs more frequently in this class of diseases than in any other class, or indeed in children who have no disease, but I have come to look upon certain prodromal signs with a great deal of apprehension. Of 1,371 cases in the hospital from January 1, 1881, to January 1, 1891, 22, or about one and one-half per cent., developed meningitis. The greater number in any one year was in 1888–89, where there were 139 cases, with seven developing meningitis, giving a mortality of a little less than five and one-half per cent. There were two years in which no deaths occurred from this complication. On general principles one would suppose that this complication might be averted by allaying excitement and by removing as early as possible the focus of disease from the end of the bone. I know of nothing practical to offer and there is nothing to add in the way of treatment.

Abscess.—Roughly speaking, about fifty per cent. of all cases develop abscess at some time during the progress of the disease. Statistics show that joints which get early protection and prolonged protection develop abscess much less frequently. Still, the question as to what is the correct and proper treatment is a relative one. It is generally agreed among surgeons that protection and immobilization should be employed in the management of a given case, yet the details vary and it is a rare thing for a child with joint disease to get uninterrupted and continuous immobilization. For instance, one surgeon employs a portable splint by day and weight and pulley by night; the details of the management are left with the family. Another surgeon employs a splint night and day, but allows the family to change straps and buckles. In this way the principle is not thoroughly carried out. Again, another surgeon uses weight and pulley in bed, with or without fixation of the pelvis. So that we are not in a position at present to determine whether the abscess depends upon the treatment employed or whether it depends upon the extent of the disease at the outset. It is my conviction that, as we progress in therapeutics and especially in early diagnosis, abscesses will be very infrequent.

Suppose they do come, then how can they be best managed? For many years I believed it was better to leave the abscess alone than to attempt to remove it by operative procedure. My plan to-day is this: aspirate as soon as the sac can be made out; after removing the contents inject an emulsion of iodoform and sterilized oil, apply compresses and keep the child quiet for twenty-four hours; repeat this procedure in a week or a fortnight, according to circumstances, the chief circumstance being the refilling of the sac. If the abscess is large when it comes under observation, and is in the way of efficient mechanical treatment, I make a free incision, do

[1] Read before the Practitioners' Society, New York, February 5, 1892.

my best to obliterate the sac, wash thoroughly with sublimate, flush with peroxide of hydrogen, dry with iodoformized gauze, suture the long incision made, and drain at the lowest portion. At the hospital last year, in the abscesses aspirated without the injection of oil and iodoform, fifty per cent. disappeared after one or more aspirations. However unsurgical aspiration may appear, I think it can easily be demonstrated that even large abscesses under this treatment grow smaller, and when they do open spontaneously or must be opened by incision, pursue a much more benign course. So that I am prepared to say that aspiration is not a useless procedure, and that in the hands of a practitioner it is much safer than free incision.

After all, an abscess is not so dreadful a complication or serious a phase of joint disease. I have long been convinced, and this conviction has been reached by carefully observed statistics, that in ostitis of the ankle an abscess is good for the ankle. Patients get well with better ankles, much more useful every way, where an abscess occurs, and we have the satisfaction of knowing that the foci of disease have been relieved by this discharge.

While closing this part of my paper, a lady calls to get my advice about an old patient in the hospital many years ago. She tells me that her daughter, now nineteen years of age, was a patient ten years ago in the hospital for eighteen months, suffered from what we called caries of the ankle, was in a wheeled chair the better part of that time, had several abscesses, that these took a natural course, that the child was subjected to expectant treatment, and that for at least eight years she has had no trouble with the ankle, it is marked with cicatrices, that the functions, from all I can learn, are perfect. She tells me that no one can detect any limp, that she never complains of the joint, that she is able to dance and use the limb all day. I questioned her very closely about this final result, and I am satisfied that what she states is true, because I have seen many cases similar to this.

In striking contrast, let me narrate one in hospital twenty years ago, in the ward for at least two years, under treatment for caries of the ankle, where suppuration never did occur. Ten years after her discharge I found the girl living at service in the family of a medical man. While she was in good health and was able to hold her place, yet the doctor told me that very often she made a misstep in walking, turned her ankle, and was laid up for two or three days with pain and discomfort; that she was ever conscious of having an ankle. I examined the patient and found a degree of tenderness remaining, although no infiltration; found the functions not quite as good as in the other ankle, but a sensitive joint. I have found just such cases among my knee patients and also among the hip patients. While I do not wish to say that it is well to court abscesses and to allow the disease to progress so that an abscess will form, I do mean to say that if an abscess should come it is perhaps better for the patient, provided we can conduct the case to a successful issue.

Amyloid Degeneration.—A complication that appears in the later stages of the disease, after prolonged suppuration, is familiar to us all under the name of amyloid degeneration. Fortunately I do not see so many of these cases as I did in former years, because I am all the time making strenuous efforts to cut short the suppurative process. Sinuses are curetted frequently, abscesses are cleansed, tuberculous foci and bone are removed, the best hygiene is sought for the patients, hospital life is sometimes terminated, and in this way I am sure that the drain on the system is much less.

Many years ago, in an extensive analysis of cases of joint disease, I found that prolonged suppuration must occur in children with tuberculous family histories to produce amyloid degeneration.

When one is satisfied that amyloid changes have already supervened, radical measures naturally are suggested. If the patient suffers from a tuberculous affection of the knee or the ankle, amputation is preferable to excision. The literature of the subject shows that a certain number of cases are cured after amputation. The cases recorded are well reported, and the character of the surgeon so reporting is sufficient to substantiate the claim. In a few rare instances the process has been cut short and resolution has taken place after excision. In still a rarer number of instances resolution has taken place where no operative interference has been attempted. The weight of evidence, however, is in favor of amputation. In looking over the statistics of excision of the hip, a few where amyloid degeneration existed and where the excision failed to give any relief have obtained perfect relief and the patient has been cured by a subsequent amputation.

Compression Myelitis with Paraplegia.—The next and last complication which I shall bring up for discussion is compression myelitis with paraplegia. I trust I shall not be looked upon as straining a point when I class Potts' disease of the spine as a joint disease. Compression myelitis, of course, does not occur as a result of disease in any other joints than those of the spinal column. The extent and the degree of the paralysis is not determined by the amount of angular deformity. It has long since been demonstrated that a most obstinate compression myelitis may occur in a case where there is a minimum amount of osseous deformity. I have, at present, two cases in the hospital, under treatment, where the deformity is scarcely appreciable. The bone lesion is in the cervico dorsal region. Both parents have suffered, and one is now suffering from brachial paraplegia as well as paraplegia in general. One has recovered from the brachial paraplegia, while the other has been relieved in a measure, yet to the paralysis is added an occasional painful spasm of the muscles, controlled only by a cautery to the back.

The views expressed as to pathology differ a little, yet the differences are so slight that it is only necessary to state that, in a general way, most of the paralysis is due to an inflammatory thickening of the pachymeningeal tissue, in fact, a pachymeningitis, with secondary involvement of the meninges and cord itself. In many instances a transverse myelitis occurs with secondary changes in the column. There are undoubtedly a certain number of cases where no myelitis does occur, where it would seem that the disturbance is purely reflex, where the circulation is at fault, and when relief is afforded to the circulation prompt relief takes place in the limbs themselves.

The ease with which the spinal canal can be opened by operation has prompted many surgeons to relieve this compressed cord by means of the forceps and scissors. There are on record a few remarkable instances of relief, yet it is my impression that the majority of cases have not improved, or at least have derived no permanent benefit, from the operation. I make this statement rather guardedly, because the final results have not been furnished. The mechanical treatment has been so satisfactory in my hands that I have not resorted to operation. I take hold of a case, for instance, with a great deal of confidence, and the plan of treatment is as follows: Extension and counter extension in bed by means of weight and pulley or elastic straps; the patient is placed on a hardish bed, on rubber sheeting, which is kept powdered with boracic acid or something similar; an occipital and frontal strap is secured to the head so that great force can be employed, if need be, with straps, and fastened to the head of the bed by means of some elastic tubing; this serves as counter-extension; about the pelvis and loin a canvas lacing is secured, to the sides of which, just above the trochanters major, a piece of strong webbing with buckles is attached; a long piece of webbing is attached to each buckle and passes down to the foot of the bed, over a pulley, and at the end of the webbing a weight is attached. The traction is regulated by the sensitiveness of the skin over the pelvis. Potassium iodide is administered in in-

creasing doses, beginning, say, at five or ten grains in vichy, three times a day after meals, and pushed at the rate of five grains a day increase up to eighty or a hundred grains three times a day. If the case prove very obstinate and the patient suffers from muscular spasm, that is, if the reflexes are very much exaggerated, I employ, once or twice a week, the small tip of the Paquelin cautery brushed rapidly and lightly over the bosse on each side of the spinous processes. In cases where the paralysis is complete it is not an uncommon thing to see improvement begin within three or four weeks, and an encouraging amount of relief in two or three months. As soon as convalescence is established, that is, as soon as the patient can move the limbs about pretty freely, although requiring some effort, can flex and extend the toes, although feebly, I employ a plaster-of-Paris jacket with head-spring, get the patient out of bed into a wheeled chair, continue the iodide. Within two or three weeks the child can walk about, and I feel pretty sure that a cure is not far distant. I find it necessary to continue a snug-fitting spinal support for a year or two after the patient is relieved of the paralysis. I never employ electricity or massage or anything that tends to bring on muscular spasm. I believe all excitation should be avoided. After convalescence has been fully established, and where I find that secondary changes have taken place in the cord, producing atrophy or loss of power of individual groups of muscles, then massage or faradism, and even supporting apparatus, may be employed.

The Sequelæ.—Chief among the results of joint diseases is deformity. The kind of deformity depends upon the joint or joints involved. Take, for instance, the spinal column. We have a gibbus or kyphosis, which is very often the first sign that the practitioner's attention is called to observe. The average medical man is so unfamiliar with the symptoms and aches and pains that precede the stage of deformity that he seldom thinks of making an examination of the column. This very day a medical man, thirty-four years of age, was referred to me by Dr. Janeway, who had been consulted on account of a distress in breathing, and, failing to find any pulmonary lesion, looked the case over in his thorough way and found a kyphosis or bosse in the middle and lower region. This physician has suffered for four years with pain referable to his spine; has continued in the practice of his profession, has sought advice frequently from his confrères, but it remained for Dr. Janeway to discover this prominence in the spinal column. A year ago he had a compression myelitis and had incomplete paraplegia for many months. Spontaneous resolution took place, and now he has just begun to show signs again of a recurring compression myelitis.

Where the disease invades the upper dorsal and cervical region, distortions of the head are apt to occur, a peculiar deformity of the shoulders, and one recognizes deformity earlier than where the disease invades a different part of the column. Where the lower dorsal and lumbar regions are involved the gibbosity is by no means the least distressing deformity that may occur. The chest-walls themselves are involved, the thoracic and abdominal cavities are altered in shape, the viscera are compressed, a lateral deviation or scoliosis often results, painful neuralgias occur as a result, the child is stunted in growth, and, indeed, there seems to be no end to the catalogue of deformities that may result from an unprotected spinal column the subject of disease.

Where the hip is involved one of the most common deformities we have to deal with is a partial ankylosis, with flexion and adduction of the thigh. This causes a lordosis of the spinal column and an extremely awkward gait, and should be corrected before the age of puberty. The methods of correction are simple enough, only they require persistence in attention and detail. Even before the case is cured and before we can begin to speak of sequelæ, prevention of deformity should be considered and prompt measures resorted to. It is extremely rare for bony ankylosis to take place. Under ether, therefore, adhesions can be overcome by manual force very frequently. I do not mean brisement force in any sense of the term. If, for instance, a case presents with little or no shortening, but with flexion and adduction, accompanied by painful spasm, and without any abscess, or even if abscess is present, it is very good practice, in my judgment, to anæsthetize the patient, slowly pull the limb into better position, doing the minimum amount of violence to the hip, discontinue the anæsthetic, put the hip up in plaster-of-Paris, securing perfect immobilization to the joint. The plaster should extend from the foot to the free ribs. This procedure is seldom followed by any acute symptoms, the little sprain produced is soon cured by the rest, and at the end of a fortnight a splint can be applied which will protect the joint against further trauma. I have no hesitation in recommending this method of correcting deformity, I know it can be abused, but one is less apt to abuse a hip by this process than by the use of ill-fitting apparatus. We are all familiar with the inclined plane, weight and pulley, and know just what can be accomplished by this process, yet circumstances often interfere with the proper use of the weight and pulley, the time element comes in, and we must get the limb in good position for a portable apparatus. Where the deformity has lasted for many years and where the signs of active disease have long since subsided, then the deformity can be corrected under ether by means of the tenotome or open incision for the section of muscles and bands of fascia. When the deformity cannot be corrected by section of muscles and fascia and by the employment of manual force, then an osteotomy below the trochanter minor enables one to fracture the limb and over-correct the deformity. The treatment of this fracture will depend somewhat upon the surgeon who does the operation. I invariably employ plaster of Paris, reinforced by bits of steel on the side of the limb and in front. I am well aware that many objections are offered to plaster, but I am convinced that the objections are offered by men who are not thoroughly conversant with the use of plaster of Paris. After the plaster is removed, I find it necessary, especially where I have found it necessary to shorten the treatment, to employ the inclined plane with weight and pulley for one or two weeks afterward until all deformity is corrected. Then, as a matter of precaution, I employ the long hip splint for one or two months, sometimes substituting for this the jointed hip splint, which is worn for two or three months longer. I know nothing that has succeeded so well in my hands as this osteotomy below the trochanter minor.

Under the deformities that occur at the knee as the result of disease, we have flexion, subluxation, luxation, and genu valgum. Of course it is desirable to prevent deformity here as well as in other joints. This can be done best by making an early diagnosis and by a thorough knowledge of the clinical history of the disease. Given these two factors, any form of splint that one is familiar with can be employed as a prevention of deformity. The correction is often difficult, however. I have on so many occasions presented what we term at the hospital the Billroth splint that I feel that I shall be trespassing on your time if I go into details on this occasion. I merely wish to say that with poor flexion and a moderate amount of subluxation I have no hesitation in assuring the parent or the patient that the deformity can be corrected perfectly without operative interference. The plan is to incorporate tin splints, jointed at the knee, into a plaster of Paris bandage, building in the popliteal space quite heavily with plaster, leaving an elongated opening over the ligamentum patella. After the plaster is set make a section through the plaster in the popliteal space, then pull the limb into better position, inserting from day to day wedges of cork, increasing in thickness. To guard against the recurrence of deformity is a very essential feature in the management of the case. I know nothing better than immobilization of the limb in plaster-of-Paris for some

months with a walking-splint which protects the joint against trauma. I employ the Thomas knee splint for this purpose, and I take pleasure in showing you the apparatus this evening.

The pulmonary lesions that are regarded as a sequel to the joint-disease of childhood are so familiar to the profession that I refrain from comment. It is well known that one of the dangers that threaten a patient who has been the victim of bone disease in childhood is a pulmonary tuberculosis about puberty or shortly thereafter. I need only urge the importance of good hygiene and a kind of life that one would seek if the danger were known.

I beg forgiveness for a paper so desultory, and plead as an excuse my desire to bring out a discussion that will be worthy of the Practitioners' Society of New York.

Progress of Medical Science.

Ether and Chloroform.—Dr. Kocher has been led by his researches upon the comparative advantages of ether and chloroform to formulate the following conclusions: 1. Before proceeding to general anæsthesia, it is indispensable to examine the patient thoroughly and submit him to preliminary treatment. 2. It is useful, and even necessary in many patients, to stimulate the heart's activity by the administration of alcohol or other stimulant (tea) before proceeding to anæsthesia. 3. The patient should be put to sleep only when in the horizontal position. 4. When the subject has not been properly prepared beforehand, chloroform should never be employed. 5. When the subject is affected with heart-disease, or with any functional cardiac affection with accompanying implication on the part of the respiratory organs, ether should be preferred to chloroform. 6. The opposite course is necessary when an affection of the respiratory tract is present with hyperæmia of the tracheo bronchial mucus. 7. When the anæsthetic sleep is to be prolonged for a relatively long period, chloroform should be used first and then ether administered in small quantities to keep up the anæsthesia. 8. Chloroform should never be given mixed with a large proportion of air; during the whole duration of anæsthesia fresh air should, however, be admitted freely to the respiratory passages of the subject. 9. For long operations, or for one reason or another, the use of ether seems to be contra indicated, a preliminary injection of morphine or morphine and atropine should be made, so as to restrict as much as possible the quantity of chloroform necessary to secure anæsthesia of sufficiently long duration.—*Gazette Médicale de Paris*, October 17, 1891.

Erythema Multiforme in Typhoid.—Dr. Laufer has observed a generalized eruption of erythema multiforme in a girl of twenty-three, suffering with typhoid. A few days before death small dermic abscesses appeared about the shoulders and ankles. The autopsy revealed pneumonia as well as typhoid. In the kidneys were numerous yellow foci which consisted of pus-cells, typhoid bacilli, and streptococci. The latter were also present in the skin abscesses, and the author believes it due to their wandering to the surface that the erythema occurred.—*Deutsche Med. Zeitung*, No. 5, 1892.

A New Tropho-neurotic Disease.—Drs. Hallopeau and Larat have reported to the *Assoc. française pour l'Avanc. des Sciences*, a case in which there existed, in different portions of the body, plaques of irregular outline over which the skin was discolored, insensible to simple contact, and not very sensitive to prickings. The latter either occasioned no flow of blood, or else the escape of a little, almost black, blood of asphyxia. The hairs fell out over the patches and when reproduced grew in white. The patches were surrounded by pigmented areas, and thus presented the objective characteristics of vitiligo. They either disappeared spontaneously, or under the influence of cutaneous irritation. In the different varieties of dyschromias of nervous origin which have hitherto been described, the concomitant phenomena have consisted in changes of sensitiveness, changes in vascular supply, and changes in secretion. Now must be added, in order to include this case, changes in the nutrition of the hairy growth. In a second case there was coincident cutaneous hyperplasia, showing itself in the form of lichenoid papules surrounding the whitened patches. The grouping of the papules about the achromatic areas separates this from all previously described dermatoses, and at the same time shows that the nutrition-changes which have modified the pigmentation have also caused the hyperplasia manifested by a lichenoid eruption. The conclusions reached by a study of these cases are: 1. There exists a dermatosis characterized by achromatic plaques surrounded by papillary zones, and exaggerated pigmentation. 2. This dermatosis is probably a cutaneous manifestation of hysteria. 3. The lichenoid papules may be of tropho-neurotic origin. 4. They are not of necessity related to pruritus. 5. Cutaneous electrization in form of faradic baths seems to be indicated in such cases.—*La Tribune Médicale*, October 15, 1891.

Cure of Recurrent Erysipelas.—Dr. Lavrand relates the case of a woman who had repeated attacks of an erysipelas-like erythema, beginning at the sides of the nose, sometimes as often as twice in the month, but usually not proving severe. She suffered from chronic pharyngeal catarrh as well as hypertrophy of the middle and lower turbinated bones. Repeated medicinal as well as galvano-caustic treatment of the nose, which was looked upon as the port of entry of the infection, was without result, and the attacks continued. Cure was effected, however, by treatment of the naso-pharynx, and especially by the removal of adenoid vegetations found there, and it was thought that the tissues made vulnerable in this location offered the real entrance for the erysipelas cocci.—*Deutsche Med. Zeitung*, No. 5, 1892.

Exalgine.—Dr. Désiré relates some very interesting cases observed at the Lariboisière Hospital in Paris. In every case the drug was given in four-grain dose at two and at four P.M. In some instances this was progressively increased up to twelve grains or more. Thirty-two cases suffering from nearly every variety of pain were treated, and thirty were either greatly benefited or permanently cured. Vertigo was complained of in a few cases, but the dose was not decreased, and in one the vertigo disappeared while the dose was being increased. In some hundreds of cases of throat pains, dysphagia consecutive to tuberculosis, etc., great amelioration for long intervals was secured. It has also been found of great value in traumatic pains.—*Journal of Nervous and Mental Diseases*, January, 1892.

Abortive Treatment of Gonorrhœa.—Dr. Diday gives his views on the abortive treatment of gonorrhœa in the *Gaz. des Hôpitaux*, October 13, 1891. He believes, 1. That in the early stage every gonorrhœa can be aborted. 2. That the abortive treatment is neither locally nor constitutionally dangerous. If the meatus has already become œdematous it is probably too late, and surely so when the discharge has become well established. There are two methods: 1. A strong solution may be introduced for a short period. 2. A weak solution may be allowed to remain a longer time in the urethra. A five per cent. solution of nitrate of silver should be allowed to remain, according to the amount of pain, from forty seconds to a minute and a half. After the fluid has been injected the finger is to be applied to the meatus, but the orifice not squeezed, as this keeps the fluid out of the fossa navicularis. Pressure can be made along the canal to force the fluid more deeply in. After about two hours a free discharge takes place, and only after four days can the result be certain. If a discharge persist after this it may still be due to the burning, in which case it will cease of itself within a few days

more. The abortive method is regarded as worthy of trial in view of the serious complications at times following a gonorrhœa.

Treatment of Hydrocele.—According to the *Indian Medical Gazette*, no treatment succeeds better in ordinary cases of hydrocele than the injection of tincture of iodine. It does, however, cause pain and may produce pyrexia, and iodism has resulted from absorption. Dr. Milliken has treated 54 cases by injection of strong carbolic acid: 9 were not subsequently seen; 4 remained under observation, and 36 were cured; 4 required two injections, and 5 had to be injected three times. There was no sloughing, and no patient was more than a day away from business. Five to twenty-five minims of liquefied crystals of carbolic acid are injected through the cannula which evacuated the fluid. After removing the cannula the sac is lightly kneaded to distribute the acid over its inner surface.—*Bristol Medico-chirurgical Journal*, December, 1891.

Sublimate Poisoning.—Dr. Nesemann relates an instance of constitutional poisoning after washing out the vagina with a 1 to 4,000 corrosive chloride solution for ten days. An eruption suddenly showed itself, first on the mons veneris, then over the hips and extremities, consisting of separate dark-bluish-red ecchymotic spots and petechiæ; at the same time there was increased flow of saliva and gingivitis, headache, weakness, loss of power in the legs, lack of appetite, etc., all in a woman previously strong and well. As soon as the sublimate injections were stopped and a permanganate wash substituted, the symptoms all disappeared, including the ecchymoses. The author thinks an idiosyncrasy must have existed in this instance, for allowing that fifty cubic centimetres remained in the vagina, only about one and one-quarter centigramme could have been absorbed daily.—*Deutsche Medizinische Zeitschrift*, No. 1, 1892.

Fibro-sarcomatosis. — Dr. Langenbuch recently presented at the Freie Verein der Chir., in Berlin, a patient who had had several months before about eighty fibro-sarcomata scattered over the skin's surface. An energetic treatment with iodides and arsenic had already resulted in a decrease in the tumors, when an erysipelas suddenly developed and spread over the entire surface. The consequence of this was that, within the space of five days all the sarcomata had disappeared and the skin had become normal. After the space of a year a slight recurrence had taken place, and a tumor the size of a plum was to be seen in the region of the neck.

Monstrous Hypertrophy of the Prostate.—Dr. Adler presented at the Freie Verein der Chir., in Berlin, the following history: A patient of sixty-six years had for fifteen years suffered from difficulty in urination, but had used the catheter without trouble until recently, when severe bleeding was occasioned by its introduction. Suprapubic and, subsequently, perineal cystotomy were done, but no permanent relief was afforded. The blood oozed from the prostate as from a sponge. The Paquelin cautery was employed, but death soon took place. The prostate measured 6½ centimetres wide and 20 centimetres long.

Intestinal Antisepsis.—Dr. Dujardin-Beaumetz recommends the following formula as a satisfactory intestinal antiseptic:

Salol,
Salicylate of bismuth,
Bicarbonate of sodium, āā 150 grains.

To be divided into thirty powders in capsules. One capsule to be taken before breakfast and before dinner.

—*Therapeutic Gazette.*

Intestinal Perforation in Typhoid.—Dr. Fitz (*Boston Medical and Surgical Journal*, Nos. 14, 15, 1891), writing upon the prognosis and treatment of intestinal perforation in typhoid fever, says: Most cases of recovery from symptoms of perforation of the bowels in typhoid fever are those in which an attack of appendicitis is closest simulated, while the fatal cases are, in the great majority of instances, those in which other parts of the bowel than the appendix are the seat of the perforation. The suggestion of laparotomy was first made by Leyden in 1884. The first operation for the relief of the symptoms caused by a perforating typhoid ulcer of the intestine, where there is no question as to the nature and seat of the lesion, was performed in 1887, by Lücke. Successful results of operation for the cure of circumscribed peritonitis in typhoid are comparatively few. Out of twenty-seven collected cases of peritonitis in typhoid, whatever may have been the cause of the former, though often attributed to intestinal perforation, three recovered after operation, seventeen after resolution, and nine after the spontaneous discharge of the pus. The appropriate treatment thus indicated would be delay until a probably encapsulated exudation proved unduly slow in absorption. An immediate or early laparotomy for the relief of the peritonitis seems advisable only when the patient's condition is exceptionally good. Should the signs of the exudation persist a week or more, and the general condition of the patient permit an incision, surgical treatment would then be strongly advisable. The patient may live for weeks after perforation has taken place. In brief, immediate laparotomy for the relief of suspected intestinal perforation in typhoid fever is only to be advised in the milder cases of this disease. In all others, evidence of a circumscribed peritonitis should be awaited, and may be expected in the course of a few days. Surgical relief to this condition should then be urged as soon as the strength of the patient will warrant.

Puncture in Chronic Hydrocephalus.—Dr. Karnitzky (*Arch für Ped.*, August and October, 1891) reports five cases of chronic hydrocephalus treated by puncture. In none of the cases did any complication follow the operation. In two cases the child died; in one the head was tapped twice, in the other five times; in the latter death was due to diarrhœa, and considerable improvement followed the first tapping. In another case, tapped five times, the child was growing rapidly worse when last seen; one case was only under observation five days; in the fifth case, a female child eleven months old, with a very large head, with extremely thin bones, six punctures were made during the course of a month; the circumference of the head was reduced from seventy to sixty-two centimetres, and when at the end of this time the child ceased to be brought for treatment, it appeared to be doing well.—*British Medical Journal.*

To Dissolve Cocaine.—Squibb recommends the use of a half of one per cent. solution of boric acid to dissolve cocaine, this amount being needed to prevent decomposition.

The German Surgical Society.—The twenty-first Congress of the German Surgical Society will be held at Berlin in Whitsun week, from June 8th to 11th, under the presidency of Professor von Bardeleben. It is hoped that the Langenbeckhaus, the formal opening of which has been fixed for June 1st, will be ready for the accommodation of the Congress. The first general meeting will be devoted to a discussion on "The Surgical Significance of the New Firearms," to be introduced by Professor P. Bruns. Another specially interesting feature of the Congress will be a debate on "Anæsthetics," to be introduced by the presentation by Professor Gurlt of the report of a collective investigation on the subject.

Dr. James Ross, of Manchester, England, died recently of cancer of the stomach. He was fifty-five years of age, and was born in Scotland. Dr. Ross was best known for his treatise on "Nervous Diseases," a work which showed intellectual qualities of the highest kind. He also made important contributions to the subjects of aphasia and neuritis.

Clinical Department.

A MIXED EXANTHEM PROBABLY SCARLATINOUS.

By L. HARRISON METTLER, M.D.,

CHICAGO, ILL.

The mixed character of its cutaneous eruption obscured somewhat the diagnosis of the following case, though most of its symptoms seemed to indicate scarlatina. It is interesting, at all events, on account of its being an unusual form of the exanthemata.

E. J. H——, a young man, twenty-five years of age, came to my office, on the morning of February 20th, with a fever of 101.5° F., a highly inflamed throat, and a marked swelling of the glands just back of the right sterno-mastoid muscle. While attempting to extinguish a fire a few days earlier, he was exposed to cold and dampness. This he treated with the usual home remedies, and the next day considered himself quite well. His average health is excellent, and his active, buoyant temperament does not readily yield to an attack of sickness.

The day before he called to see me he was taken, about 3 P.M., while engaged at business, with a severe chill, violent headache, nausea and vomiting, and general aching throughout the whole body. His mother says that when he came home in the evening he had an unusually high fever, his skin was hot and dry, and he was extremely restless. He complained of the parched condition of his mouth, the pain upon swallowing, and the soreness of the swelling in the right submaxillary region. A hot bath and quinine and whiskey were taken, but he continued restless and wakeful during the night.

It was about nine o'clock the next morning when he first came under my observation. I found the temperature then to be 101.5°F., the pulse 100, the tonsils and fauces congested and somewhat swollen, and the glands at the right angle of the jaw greatly enlarged and tender. The swelling of these glands extended somewhat down the side of the neck, along the posterior border of the sterno-mastoid muscle. Swallowing was extremely difficult, but pressure externally over the tonsils did not elicit much pain. The tongue was coated with quite a thick, brownish-yellow fur, extending in two broad parallel lines, thus leaving the middle, edges, and tip clean and red. The headache was the most intolerable symptom complained of. There was some nausea and general aching of the whole body. At this time the patient was entirely free from cough or other signs of broncho-nasal catarrh. The patient being subject to occasional attacks of quinsy, I diagnosed the present trouble as tonsillitis, and placed him on treatment for the same. This consisted of rest in bed, hot mustard foot-bath, ice to the throat, externally and internally, a chlorate-of-potash gargle, two grains of quinine four times a day, and two drops of belladonna tincture, with one drop of aconite-root tincture every half hour, hour, or two hours, according to the condition of the pulse and temperature. At night the swollen glands were rubbed with camphorated oil and the throat freely gargled with hot milk.

About 1 A.M. the first night after I had seen the patient I was hurriedly sent for on account of the sudden appearance of a bright red rash over the entire surface of the body. The young man was resting easily so far as his own sensations were concerned. The excessive diarrhœa, amounting to ten or twelve watery stools in twelve hours, had stopped; the headache was gone; swallowing was much less painful; there was a decided diminution in the swelling of the neck; the restlessness was followed by quiet, and the general aching of the body had disappeared. The temperature registered 101° F., and the pulse numbered 96, but both the temperature and the pulse had been lower since he commenced taking the belladonna and aconite drops every two hours. In some respects the rash had much the appearance of scarlet fever, for it was uniformly distributed over the entire body; there were no intervals of healthy-looking skin, and the color disappeared under pressure of the finger only to quickly reappear when the pressure was removed. The coloration was more pronounced in some of the dependent portions of the body, such as the calves of the legs, the back of the thighs, and small of the back. It was particularly noticeable about the face and ears. It itched so that the patient could scarcely refrain from scratching himself. On the other hand, this rash had much the likeness of measles. It was rough and elevated with well-marked papulæ, and in certain localities, such as the chest, the back, the legs, and the feet, the papulæ arranged themselves into the well-known crescentic and other bizarre-shaped clusters common to measles. The papulæ were small, exceedingly numerous, and close together. They were redder than the basement skin on which they rested. Indeed, so typical of measles was the appearance of the skin that the mother of the young man, an intelligent woman and experienced in the care of measles, declared positively that she believed the case was one of that disease. The patient had already had a severe attack of measles in his early childhood, accompanied by the usual symptoms of broncho-nasal catarrh. Latterly he has suffered from frequent attacks of urticaria. I examined a specimen of his urine passed in the twenty-four hours. It was dark-yellow in color, feebly acid, and exhibited a specific gravity of 1.028, and 65.24 grammes of solids in 1,000 c.c. There was not a trace of albumin, though I employed five or six different tests for its detection. The urine was simply a febrile urine.

A day or two later there was some coryza, and on the second and third evenings the patient says he bled freely from the nose, so much so that once he was on the point of sending for me, but did not, as the bleeding stopped of its own accord. There was also later on a very slight cough without any huskiness of the voice. The cough, in fact, was so slight that the patient himself insisted he had none. Constipation succeeded the early diarrhœa and continued to be troublesome far into convalescence. On February 23d the throat trouble had entirely vanished, the rash persisted, the temperature fluctuated about 100.8° F., and the pulse varied from 76 to 86. On February 25th the patient got up, dressed, and sat many hours in an arm-chair. There was no more fever, sore throat, or other symptom, except a feeling of extreme weakness. The rash, however, still remained, less red in color, more distinctly papular, rough to the touch, itchy, and quite free from any evidence of beginning desquamation. It had none of the appearances of German measles. The tongue, though somewhat clearer, was still badly coated, cracked along the edges, and had much the appearance of the well-known "strawberry tongue" of scarlatina. The tonsils and pharynx exhibited a few insignificant patches of exudate, but were entirely free from the prodromic punctations of measles.

The patient called to see me at my office February 26th, troubled only with the excessive weakness and a peculiar rheumatic soreness about the left knee, which he attributed to the forced rest in bed. The rash had now almost entirely disappeared without desquamation. I placed the patient on a tonic treatment and urged him to remain indoors for a few days.

The prevailing epidemic is doubtless modifying the typical course of many of the ordinary diseases. Whether it had any influence in this case I am unable to say; but the marked character of some of the nervous symptoms, such as the headache and restlessness, as well as the extreme exhaustion following so short a period of illness, would seem to indicate its influence In some of its features the case was one of scarlet fever, in others, measles. While regarding it as scarlatinous, I must admit that I am loath to consider it, in view of its resemblance in some respects to measles, simply as a variety of scarlet fever.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, March 26, 1892.

SOME IMPRESSIONS OF AMERICAN SURGERY.

WE have frequently quoted the views of American physicians who have visited hospitals and clinics in Europe. It may be of interest to hear some opinions concerning our own institutions as expressed by a candid Scotch observer, Mr. Rutherford Morison. In an article entitled "Surgical Impressions of a Flying Visit to Some American Hospitals,"[1] the gentleman in question gives the result of his observations during an eighteen days' visit industriously spent in New York, Boston, Baltimore, Cincinnati, and Chicago. The first hospital described is the Roosevelt. Here he was impressed by the cramped space of the hospital proper and the magnificent possibilities of the new operating pavilion. The Vienna plan of dissecting out all buboes strikes his attention, and he thinks that in America the bubo must be a much more serious disease than in Great Britain. The practice of always using a needle-holder in inserting sutures also calls for some comment. Mr. Morison was "surprised to learn that all strictures are dealt with by internal urethrotomy. Those in the penile portion are cut only; those behind are cut, and in addition the bladder is drained through the perinæum.

"The bougies used in the after-treatment are," he says, "terrible looking weapons, and 'bougie day' did not appear to be anticipated by the patients with feelings of unmixed satisfaction. Surgical principles are not elastic enough to allow of such a radical difference of opinion and practice as I saw there and see with us. If they are right we are wrong."

The operative treatment for malignant growths he found to be carried out in a much more radical way than in England, "*e.g.*, in an ordinary case of scirrhus of the mamma it is usual," he says, "to remove a large area of skin covering and surrounding the growth, to take away the pectoralis major, divide the pectoralis minor, and dissect out from the axilla everything except vessels and nerves. The skin gap is filled up by a Thiersch's graft—an excellent method, not sufficiently used in England."

In cancer of the tongue an incision is made through the centre of the lower lip, down through the middle line of the chin and neck to the hyoid bone. A second incision crosses this, running along the lower edge of the body of the jaw from one facial artery to the opposite. The flaps so marked out under the chin are reflected, the glands dissected out, and the lingual arteries tied. The lower jaw is now sawn through in the middle line, and the floor of the mouth and tongue removed.

At Bellevue Mr. Morison attended a public clinic in which a laparotomy for pyosalpinx was performed. The observer was struck with the position taken by the operator, viz., standing between the legs of the patient. He says: "I have never seen an operation more skilfully performed; but the advantages of the position adopted would have to be very clear before a British surgeon could be persuaded to adopt it. It is not an elegant one."

At the New York Hospital an operation for appendicitis was attended. During his short stay in America Mr. Morison saw five cases of appendicitis, and he concludes that it is more common in America than in Great Britain.

Favorable criticism is made of the Johns Hopkins Hospital, and the writer is impressed with the advantages of the circular ward. He states incidentally that the private wards of Johns Hopkins yield an annual income of $40,000.

At Cincinnati, the American practice of putting up fractured limbs at once in plaster of-Paris bandage is noted as a novelty. He quotes the very sensible observation of Dr. Conor to the effect that there "was now a rage on the radical cure of hernia by different methods, but that he thought possibly ligature of the neck of the sac and its removal were sufficient and as satisfactory in result as more elaborate proceedings."

At Boston Mr. Morison found that everything, "including hospital, staff, nurses and all else is decidedly English. It seemed none the worse for that."

We are told that excision of the joints is something of a specialty in Boston, and Mr. Morison evidently learned several things regarding these operations.

The writer's general conclusions are that:

"American much more resembles German than English surgery. The Germans have an indescribable way of taking possession of an anæsthetized patient, giving an impression that he is entirely their own, and that they mean to do just what they like with him.

"German instruments are large, artery forceps like tongs, scissors like sheep shears, retractors like garden rakes.

"The German surgeon is seldom in doubt, and has an excellent embryological, bacteriological, and pathological explanation of all his cases and results. If there is any mistake, something is to blame, not the surgeon.

"Then there are other German specialties, such as metal-handed knives, the invariable introduction of needles by a holder, the wearing of special operating apparel, the strict attention to asepsis and antisepsis, and the selection of only such operations as can be performed with deliberation and in open daylight. All have more or less influenced American surgery.

"Results are, after all, the test, and on these a judgment must be formed, and from this standpoint my belief is, that if English surgeons do not wish to be overtaken, they must put their best foot foremost."

Our own conclusions from reading Mr. Morison's very impartial observations are that American surgery is well abreast of the best surgery abroad, and is probably better

[1] Edinburgh Medical and Surgical Journal.

than that in Great Britain and France. This is not said in any vainglorious spirit but is a fair deduction from the impressions of an intelligent and observant foreigner.

SCARLET FEVER AND ITS TREATMENT.

The *Times and Register* publishes, under date of March 12th, a "Scarlet Fever Number," for which the excuse is the existence of a not very severe epidemic of the disease in Philadelphia. Very little, we are told, has been written upon scarlatina during the past year; the whole world contributed but fifty-three papers on this subject during 1891, according to the *Index Medicus*. Scarcely any item of importance has been discussed except the occurrence of scarlatina in animals; and this has excited practically no comment on this side of the Atlantic. Of the two special methods of treatment advanced lately, neither Illingsworth's biniodide of mercury nor Wilson's chloral induced a single paper in 1891. Inquiry among many active practitioners has failed to discover anyone who had employed either.

The articles in the *Times and Register* bear mainly on the subject of treatment and prophylaxis. Dr. K. B. Page dwells on the value of hydrotherapy. Dr. W. B. Stewart places his main reliance upon infusion of digitalis. Dr. W. R. D. Blackwood gives little medicine, and does not care much about high temperatures, unless they are above 105° F.; he doesn't worry the kidneys with diuretics, and he pins his faith on water internally and externally, with supporting treatment. Dr. E. Chenery gives hyposulphite of soda every hour or two for a time. Among other therapeutic notes the following are recorded:

Waugh describes a case of malignant nasal scarlatina that recovered under the profuse application of peroxide of hydrogen.

Manning advises the use of boric acid and glycerine for pharyngeal scarlatina.

Thorne claims striking results from the use of oil of eucalyptus internally and applied to the skin, with carbolic and tannic gargles.

Caiger has analyzed 1,008 cases, with a mortality of 4.67 per cent.

Hughes recommends nitro-glycerine in threatened nephritis.

Jamison accelerates desquamation by employing antiseptic inunctions during the whole course of the attack. He recommends Eichhoff's three per cent. resorcin salicylic superfatted soap.

Twenty prescriptions for scarlet fever by various authorities are given. They consist of antiseptic ointments, febrifuges, and diuretics.

Besides this we find writers quoted who believe in the efficacy of chloral, iodide of potassium, and biniodide of mercury.

There is a general agreement as to the utility of baths in hyperpyrexia, and of stimulants, antiseptic ointments, and gargles.

But it seems unfortunate that so much divergence of practice exists as to internal remedies. The profession would dignify itself by affirming, for example, whether any internal remedies are really needed in uncomplicated cases, and what these remedies should be. There should be more harmony also as to the character of the local applications, which now vary from the useless boracic acid to the toxic, and perhaps equally useless, corrosive sublimate solutions.

The untrustworthiness of sulphur fumigation as a disinfectant is generally admitted; and the value of evaporating dishes containing antiseptics, aside from making a smell, may be questioned.

ONE WAY OF PREVENTING VENEREAL DISEASE.

The Dutch colonial authorities have adopted a novel, if not exactly moral, mode of keeping down syphilis in their armies. Formerly venereal disease was very prevalent among the Dutch troops stationed in colonial garrisons, 211 cases in every 1,000 soldiers being the average number. This has been now reduced to only 75 per 1,000 by a system of what might be called enlisted prostitution. According to the *Lyon Médical*, each soldier in barracks is allowed to take a mistress from among the native women, and these are registered and subjected to military discipline. If taken sick they are treated in the army hospitals, and are reckoned in the non-combatant portion of the service They number over 10,000, while there are about 30,000 soldiers. This is no doubt a very effective measure of prophylaxis for the men, but what about the ten thousand native women who are served up for the delectation of their Christian conquerors?

DRUNKENNESS AND FRACTURE OF THE SKULL.

A number of striking cases have occurred lately showing how easy it is to mistake symptoms of fracture of the skull and intra-cranial injury for alcoholic intoxication. This is especially difficult when the patient is both alcoholic and apoplectic. In a recent lecture on "Neurological Fragments," by Dr. Hughlings Jackson, this point is dwelt upon and some interesting illustrations given. "It is well known," he says, "that men fatally ill from cerebral lesions are sometimes locked up in police cells for drunkenness. It needs insisting on that there may be, from grave intra-cranial lesions soon causing death, not only insensibility, but manner and conduct like that of a person partly intoxicated by alcohol. Dr. Stephen Mackenzie and I have recorded a fatal case of meningeal hemorrhage producing a condition which, without the history of onset, would—certainly by the non-medical—have been taken for drunkenness. The patient was violent, swore, and, what is more striking, there was a purposive action; the patient got the chamber utensil from under his bed and used it. At the London Hospital we occasionally have under care men who, after sucking raw spirits out of a cask, are seemingly as deeply comatose as other men are after large and fatal cerebral hemorrhage. Without the history of the circumstances and of the mode of onset, the diagnosis of apoplexy produced by alcohol from that produced by cerebral hemorrhage is very difficult, and may be impossible. For an hour or two after injuries to the head there may be a condition very like that of a man slightly drunk."

The fact that diagnosis is difficult in these cases is, as a

rule, no excuse for serious errors in treatment. Few instances occur in which careful examination will not lead the surgeon, at least, to suspect something more than drunkenness. If there is any doubt, the patient should receive the benefit of it. This point, however, should be further borne in mind: Surgical intervention is never indicated except when the locality of the intra-cranial hemorrhage is surely shown by the external injury or by paralysis or convulsions.

We think that the ambulance surgeons and house-staffs of our hospitals have received some pretty sharp lessons in their business of late; probably it will do them good. The average hospital interne, as soon as he has been adorned with a little authority, is too apt to lose his head and fancy that he is an easy master of all medical and surgical problems. The qualities of modesty and conscientious devotion to their work will admirably become these young men, and save them from the perhaps too severe criticisms of an unsympathetic public.

WHERE THE NOISE COMES FROM.

A FRENCH physician of an inquiring turn of mind has had his curiosity excited by those mysterious noises which sometimes roar around the equatorial zone of charming woman, especially if she has been indulging in unlimited bonbons, and set himself about solving the problem of their origin. He thinks he has done so, and his conclusions form one more indictment against the destroyer of the health, the grace, and the beauty of form of the gentler sex—we mean the corset. The pressure of the stays causes, he says, a constriction of the stomach dividing it into two lobes, and during respiration the gases and liquids contained in the organ pass alternately from one to the other lobe. Thus during expiration the diaphragm ascends, removing pressure from the upper lobe, while the lower lobe is compressed by the abdominal muscles. The air and fluids are thus forced into the upper lobe, and rumble and whistle as they squeeze through the constricted zone in the grasp of the corset. During inspiration the conditions are reversed, and the noisy current runs the other way. The sounds cease as soon as the stays are taken off, and reappear when they are again applied. The moral is obvious. Of course it is.

Methylene Blue.—A case of retinitis, due to acute Bright's disease, has been treated successfully with this drug in France by Dr. Gillet de Grandmont. He gave it to a patient whose urine contained a considerable quantity of albumin, in doses of two centigrammes three times a day. It caused a marked improvement, the renal symptoms abated, and the retinitis disappeared so rapidly that the sight was normal in four days. Was this a coincidence, or was the improvement due to the milk diet, which, in all the reported cases, has been strictly adhered to? Methylene blue is excreted by the kidney, and has the curious characteristic of turning the urine a deep green. Dr. G. Paul proposes to take advantage of this property to produce a moral effect upon hypochondriacs and malingerers. A dose of from five to ten centigrammes gives rise to decided coloration of the urine without causing any other symptom.—*The Lancet.*

News of the Week.

International Congress of Gynecology and Obstetrics.—The first session of this Congress will be held in Brussels, September 14 to 19, 1892. Three leading questions will be offered for discussion: 1. "Pelvic Suppurations," referee, Dr. Paul Segond, of Paris. 2. "Extra-Uterine Pregnancy," referee, Dr. A. Martin, of Berlin. 3. "Placenta Prævia," referee, Dr. Berry Hart, of Edinburgh. The fee for members participating in the first session is thirty francs. This will entitle the holder to a copy of the Proceedings of the Congress. Life membership may be secured by the payment of three hundred francs. In connection with the Congress there will be an international exposition of instruments and appliances, pertaining to gynecology and obstetrics. All communications pertaining to this Congress should be mailed direct to the American Secretary, Dr. F. Henrotin, 353 La Salle Ave., Chicago, who will promptly furnish all information. All notifications to be forwarded should be received by August 1st.

Death of Professor Edward A. Freeman.—Death loves a shining mark, but in these days it is not often such a disease as small-pox that he uses in his archery. The death of Professor Freeman from this disease seems as unnecessary as it was sad and unexpected. We shall be interested, when further details are given, in learning whether the distinguished professor was an anti-vaccinationist, or had neglected vaccination, or whether perhaps it was one of these cases in which vaccination failed to protect. The premature death of wise and useful men is always to be deplored, but most of all when it is the result of a contagion.

A Death from Chloroform occurred recently in the practice of a physician of this city. The patient was a man of about fifty-five years, upon whom amputation of a finger was to be performed.

The Surgeon who wishes to be aseptic is allowed to have nails one millimetre (0.001) long.

The Mistake of a Great Diagnostician.—A tale is going the rounds here now which illustrates how the great men sometimes trip up, and which can serve the purpose of making the little fellows more cautious, but at the same time of giving them courage. I have it directly from the lips of Professor Kundrath, the *chef* of the Pathological Institute, and there is no question that the story is entirely true. There came one day a patient to Professor Nothnagel. This patient had a very large area of dulness over the upper abdominal and lower thoracic regions of both sides. He also gave a history of having had a dog with whom he had associated a great deal. The case was very plain to Professor Nothnagel as echinococcus, and he lectured on it at great length for an hour before his class of students. Having served this good purpose the patient was sent to Billroth's clinic for operation. A laparotomy was performed, but, wonder of wonders! the liver was all right, only perhaps a trifle smaller than usual. The spleen was also without fault, and it then became apparent that the trouble was in the thoracic instead of in the abdominal cavity. The abdomen was closed up—and the patient died a few days

afterward. The pathologist—the terrible, cruel pathologist—demonstrated a pericarditis with effusion !—Vienna Correspondent *American Practitioner*.

A Bill to Cripple the Library of the Surgeon-General's Office.—Under the provisions of the Army Appropriation Bill, reported by the Military Committee to the House of Representatives, the usual annual appropriation for the Library of the Surgeon-General's office, United States Army, is cut down one-half viz., from $10,000 to $5,000. If this is not changed, either in the House or in the Senate, the result must be that the formation of a complete medical library at Washington, which has been going on so successfully for the last ten years, must be stopped.

To Investigate the Subject of Immigration—The National Senate and House Committees on Immigration have come to New York and have begun to take evidence as to the character of the present immigration, with a view to formulating a policy which will exclude at least the more undesirable of the enormous number of foreigners who annually come to this country.

College Commencements.—The Atlanta Medical College held its Commencement on March 2d, and the Southern Medical College on March 3d. Both institutions graduated large classes.

A New Medical Journal, called the *Practitioner's Monthly*, has just appeared. It is published at Kingston, N. Y., and edited by Drs. C. L. Dodge and J. Chambers

A Bill to Help Criminals and Quackery is before the State Legislature. It reads thus: "Every person who shall entice, induce, or inveigle any other person to violate any statute or commit any crime, for the purpose of informing against such person, or in order to become a witness on the trial of such person for such crime or offence, shall be deemed and held to be an accomplice in the commission of such crime or offence, and shall be subject to the same penalties and punishment as is provided by law for the offence or crime committed." The special medical interest in this lies in the fact that it would at once paralyze the efforts of our County Society to secure evidence against quacks; it would give them all a new lease of life and undo the work of years. We are glad to learn that there is an active opposition to the bill.

The War on Quacks.—A sympathetic daily contemporary says: "The regular medical faculty is winning success in the war upon quacks, one of whom has just been sent to the penitentiary for practising without a proper diploma. Other arrests of quack doctors are to be brought about as soon as possible; and an attempt is to be made to secure the total abolition of unauthorized, unlicensed quackery. The Committee on Legislation of the State Medical Society has also been actively engaged in the defeat of a bill before the Legislature through which a horde of medical ignoramuses might be let loose upon the community. Then the State Board of Medical Examiners has been put on the alert in regard to the issue of licenses to practitioners. All these signs are hopeful. We must get rid of the quacks."

Sections of the American Medical Association.—The Committee appointed at the last meeting of the American Medical Association to consider the best means for promoting the prosperity of the Sections of the Association will hold an adjourned meeting in the Hotel Cadillæ, Detroit, Mich., June 6, at 3 P.M. Dr. John S. Marshall, Chairman, 9 Jackson St., Chicago, writes that the Committee would esteem it a favor if each member of the Association would communicate in writing his or her views concerning the best measures for promoting the development of the Sections.

Mme. Lachapelle, Midwife.—The interesting historical sketch of Madame Lachapelle to which we referred in the issue of February 24th, was not from the pen of Dr. Osler, as was there stated, but that of Dr. Hunter Robb, resident gynecologist to the Johns Hopkins Hospital, Baltimore.

National Conference of Charities and Correction.—The 19th session of this organization will be held in Denver, June 23 to '30, 1892. The preliminary programme has just been published, and its topics include many of the important social problems of the day. The organization has standing committees upon State Boards of Charities, Reformatory Work, Kindergartens and Child-saving, Care and Classification of the Insane, Commitment and Detention of the Insane, Charity Organization in Cities, The Indian Policy in its Relations to Crime and Pauperism, The Colony Plan for the Feeble-minded, Immigration and Migration between States, Defensive and Preventive Measures against Pauperism and Crime, and the Co-operation of Women in the Management of Charitable and Penal Institutions. Each of these committees has charge of a general session of the Conference, and several of them will also conduct special or sectional sessions, in which they will discuss their subjects in detail. The membership of this Conference is free to all, and whosoever will may come in, on a footing of the most perfect equality. The fact that one is interested in its work makes him a member, and entitles him to a seat and a voice in its discussions. Any one desiring further particulars as to reduced railroad fare, hotel accommodations, etc., may address Alexander Johnson, Secretary, Indianapolis, Ind., who will send circulars and answer inquiries.

Hæmol and Hæmogallol—Hæmol and hæmogallol, prepared according to the directions of Kobert, are obtained from blood. Hæmol is a brownish black powder, and hæmogallol a reddish-brown. The introduction of these substances into therapeutics rests on the fact that the derivatives of the coloring matter of blood, obtained by the action of reducing agents, have a hæmatopoietic action both in health and disease. They are given in capsules in doses of from 0.1 to 0.5 gramme during the day. Healthy persons are able to take as much as 1 to 5 grammes of hæmogallol Hæmol contains traces of zinc left by design. The zinc it beneficial in slight lesions of the stomach, which might result in ulcer. Given in the form of hæmol the zinc loses its caustic action, and does not cause nausea.—*The Lancet*.

Association of American Physicians.—The next annual meeting of the Association of American Physicians will be held on Tuesday, Wednesday, and Thursday, May 24, 25, and 26, 1892, in the Medical Museum and Library, Washington, D. C. The subject selected for dis-

cussion is "Dysentery." Dr. William T. Councilman, as referee, will consider the etiology and pathology, and Dr. A. Brayton Ball, as co-referee, the symptomatology, complications, and treatment. The following papers will be presented: "The President's Address," by Dr. Henry M. Lyman; "The Production of Tubular Breathing in Consolidation and other Conditions of the Lungs," by Dr. Charles Carey; "A Contribution to the Study of Hepatic Abscess," by Dr. William C. Dabney; "Tube Casts and their Diagnostic Value," by Dr. I. N. Danforth; "The Treatment of Follicular Tonsillitis," by Dr. George M. Garland; "The Morbid Anatomy of Leprosy," by Dr. Heneage Gibbes; "A Collective Investigation in Regard to the Value of Quinine in Malarial Hæmaturia or Malarial Hæmoglobinuria," by Dr. Hobart A. Hare; "Treatment of Acute Dysentery by Antiseptic Colon and Rectal Irrigation," by Dr. W. W. Johnston; "Alcoholism," by Dr. Thomas S. Latimer; "A Study of the Seasonal Relations of Chorea and Rheumatism for a Period of Fifteen Years," by Dr. Morris J. Lewis; "A Case Presenting the Symptoms of Landry's Paralysis, with Recovery," by Dr. Francis T. Miles; "Report of a Case of Glanders, with Results of Bacteriological Study," by Dr. William Pepper; "Practical Results of Bacteriological Researches," by Dr. George M. Sternberg; "Misconceptions and Misnomers Revealed by Modern Gastric Research," by Dr. Charles G. Stockton; "The Significance of Intermission in Functional Nervous Diseases," by Dr. William H. Thomson; "Certain Toxicogenic Germs Found in Drinking-water," by Dr. Victor C. Vaughan; "Studies in Hypnotism," by Dr. B. F. Westbrook; "Pulsating Pleural Effusions," by Dr. James C. Wilson; "The Cold Water Treatment of Typhoid Fever," by Dr. George Wilkins. Papers will be read by Drs. Samuel C. Chew, A. Jacobi, Morris Longstreth, and T. Mitchell Prudden, titles of which will be announced later.

Definition of the Word "Regular."—In the army regulations, in paragraph No. 1544, there is the phrase, "and a graduate of a regular medical college." Dr. J. G. Gilchrist was appointed by the Central Iowa Homœopathic Medical Society to correspond with the Surgeon-General as to the meaning of the term "regular." The doctor asks: "Will you be kind enough to inform us what the word 'regular' means? Has it a sectarian meaning, distinguishing a particular school or class of practitioners, or does it refer to a college having the right, under the laws of the land, to grant medical degrees, and is conducted in an honorable and reputable manner?"

The reply is as follows:

"Subject—Meaning of Term 'Regular Medical College.'

"War Department, Surgeon-General's Office,
"Washington, August 4, 1891.

"*James G. Gilchrist, M.D., Committee of Central Iowa Homœopathic Medical Society, Iowa City, Ia.*

"Sir: Acknowledging the receipt, by reference, of your communication of the 1st instant, requesting a decision as to the term 'Regular Medical College,' in paragraph 1544, Army Regulations, I am instructed by the Surgeon-General to inform you that the term 'regular' is used in its most comprehensive sense, as indicating that a college is well equipped and prepared to cover the whole ground of the science and art of medicine in its teaching, and requires not less than a three years' course of study to secure its diploma.

"Very respectfully,
"Charles R. Greenleaf,
"Lt. Col. and Asst. Medical Purveyor, U. S. Army."

Another Medical College for Women is to be established at St. Paul, Minn. We are told that another such institution is needed because there are now but three in this country. There may be another medical college needed for ladies medically ambitious, but not because the supply is at present poor. There are two such colleges in this city, one in Philadelphia, Baltimore, and Chicago.

The Practice of Bleeding had just as strong foes in the seventeenth century as in the nineteenth. The people did not want to be bled; they preferred to take medicines. Most of the regular faculty, however, led by such men as Patin, believed in bleeding, and here is Patin's defence: "Our Parisians," he says, "take little exercise, drink and eat too much, hence they become plethoric. In this condition, they are almost never relieved of their diseases, if powerful and copious bleeding be not used." Besides, he adds: "For the frequent bleedings practised here, they are due to the universal debauchery and the too good-cheer that abounds. We do not bleed from custom, but from necessity, according to rules and regulations. The pretended reformers and legislators are always complaining, but give no substitute remedy. It is not a great thing to tell a man the right road to take, but it is necessary to place him on the real road he is to travel. Some foreigners blame our frequent bleedings; they know neither the cause nor the fruit nor even the necessity of the procedure. If we bleed too much, let them give us a remedy that will take its place; and what other remedy will equal bleeding? In writing, let those dissatisfied speak out. God even suffers tyrants, usurers, and those who take His name in vain to live."

For Cure of Insomnia.—Repeat twelve times the following:

Like the passionate palm that breathes all the odors of day
To the soul of the night;
Like a river that runs and frets on its turbulent way
To the quiet deep;
Like the swallow, weary of cold, that southward gleams
To her land of delight,
So the heart overfull of its sorrow flows over in dreams
Of compassionate sleep.

—Ruth Johnston, in March *Lippincott's*.

Poisoning from Arsenical Curtains.—We commend to our Boston brethren the following note, by Dr. W. Harding, published in the *Lancet*: "A good example of chronic arsenical poisoning on a large scale occurred in this asylum, and a short account of it may be both interesting and instructive. In the endeavor to make the wards of an asylum bright and cheerful, and to do this at as little expense as possible, it is not improbable that the nature of the coloring materials used may be overlooked, and that some of the gastric and intestinal disorders which disturb the peace of mind of medical superintendents may be cases of arsenical poisoning. For a long period the nurses here were in poor health. First

one and then another was laid down until, within a few months, nearly every nurse on the staff had been, or was, under medical treatment. Headache, neuralgia, gastric derangements, loss of appetite, constipation or diarrhœa, irritation of eyelids, anæmia—these were the chief symptoms complained of. Drugs did not appear of much avail, but a holiday had a marked effect for good. At last one nurse had the eye symptoms in a more pronounced form, and suspicion was aroused. In each nurse's room was a green baize curtain, used as a covering for dresses, etc. A portion was taken and examined. It was found to be impregnated with arsenic to an astonishing extent. These curtains were removed; the rooms freely ventilated; medical treatment was stopped; the symptoms disappeared, and, though some months have elapsed, have not returned. The baize was similar to that used for covering doors, etc., and was obtained from two manufacturers."

The Hospital Saturday and Sunday Collections amounted this year to $60,052.08, or about $2,000 more than last year. In the distribution the largest sum, $5,793.01 went to Mount Sinai Hospital.

The Proposed Removal of St. Luke's Hospital will no doubt be for its best advantage. But we learn that it has caused several of the visiting staff to decide to resign. The hospital, in its present convenient site, has been able to command the time and attention of men in most active practice.

The Dose of Somnal.—In the article on somnal by Dr. O. M. Myers, in the MEDICAL RECORD of March 12th, under the head of "Physiological Action," the types made the author say: "and if the dose has been excessive (℥ ij.) the arterial pressure," etc. The amount should have been ʒ ij. instead of ℥ ij.

Wholesale Insanity.—A man was lynched in Wisconsin some time ago, and at the trial of the lynchers recently, the jury very compassionately found that they were all insane, and therefore not guilty of murder. Three of the men were pronounced still insane, but the rest were said to have recovered, and so were released from custody.

The Pan-American Medical Congress in the West Indies.—Dr. William F. Hutchinson, Assistant Secretary-General of the Pan-American Medical Congress for the West Indies and Venezuela, is now on a tour of the Antilles in the interest of the Congress. Writing from St. Kitts under date of February 25th, he transmits a report of formal action by the profession, under the presidency of Dr. Branch, President of the Leeward Islands Branch of the British Medical Association, cordially approving of the object of, and pledging support to, the Congress, and nominating certain officers. At St. Thomas, Danish West Indies, Dr. Mortensen, King's Physician and member of the International Executive Committee of the Congress for these colonies, is securing the most hearty co operation of the profession. Dr. Hutchinson has had equally enthusiastic receptions at Santa Cruz and at Philipsburg, the latter on the Dutch island of St. Martin. In several instances the governors of the colonies have expressed a warm interest in the Congress, and will designate delegates.

Obituary.

D. HAYES AGNEW, M.D., LL.D.,

PHILADELPHIA, PA.

DR. D. HAYES AGNEW, the famous surgeon of Philadelphia, died at his home March 22d, in the seventy-fourth year of his age. He was born in Lancaster County, Pa., in 1818, and was the son of Dr. Agnew, an eminent physician of that section. After completing his classical education at Newark College, Delaware, he entered the Medical Department of the University of Pennsylvania, from which he obtained in due time his degree of Doctor of Medicine. He started in practice in the rural districts, but soon after moved to Philadelphia, where he early in life became a lecturer on Anatomy in the Philadelphia School of Anatomy. In 1854 he was elected one of the surgeons of the Philadelphia Hospital, and founded the pathological museum of that institution. In 1863 he was appointed demonstrator of anatomy and assistant lecturer on surgery in the University of Pennsylvania, and soon afterward became one of the surgeons of Wells's Ophthalmic Hospital. In 1865 he was elected to fill a similar position in the Pennsylvania and Orthopædic Hospitals. In 1870 the highest point of his ambition was reached by his election to the chair of Operative Surgery in the University of Pennsylvania, which position he continued to hold up to the time of his death. His contributions to surgery have been numerous and valuable, culminating, in the crowning achievement of his life, in the classical and elaborate system of surgery which at once gave him a world-wide reputation as a ripe scholar, a judicious teacher, and successful practitioner. It will long remain a standard work of its class, founded as it is upon remarkably wide surgical experience in every department of the operative art. As an operator, he was possessed of remarkable skill, and long enjoyed a varied and lucrative surgical practice, which extended over a large area of his native State. His position as a recognized surgical authority won for him the distinction of being chosen one of the consulting surgeons of the late President Garfield, whom he attended during his long and painful illness, and upon whom he performed a surgical operation with a view of extracting the murderous bullet.

Passing away at a ripe age with a long life of labor in his profession, he has left an honored name, which will always stand in the front rank of representative American surgeons.

Reviews and Notices of Books.

THE MEDICAL NEWS VISITING LIST, 1892. Lea Brothers & Co. 1891.

"THE Visiting List" is about the same as annually offered. It is convenient and useful for ordinary pocket use. It contains some valuable suggestions.

HUMAN MONSTROSITIES. By BARTON COOKE HIRST, M.D., Professor of Obstetrics in the University of Pennsylvania, and GEORGE A. PIERSAL, M.D., Professor of Histology and Embryology in the University of Pennsylvania. Part I. Pp. 88. Illustrated with Seven Photographic Reproductions and Eighteen Wood-cuts. Philadelphia: Lea Brothers & Co. 1891.

THIS beautiful work gives promise of being a credit not only to its authors but to American obstetrical literature. Its principal value lies in the photographs, which are unusually distinct. With many of the wood cuts the reader will find himself already familiar.

The text presents a carefully prepared compilation from various works on the subject of teratology, Geoffrey Saint-Hilaire's classification being followed. The paper, typography, and binding of the volume render it an *édition*

de luxe, which will form a valuable addition to the library of the specialist, perhaps also of the general practitioner. The amount of labor which must be expended upon a monograph of this character is apt to be appreciated by only a limited circle of readers; but the scholarly authors may rest assured that the work will more than "fill a gap in English literature," as they modestly express the hope in the preface. We shall await the appearance of the succeeding numbers with great interest, confident that they will continue to reflect credit upon the industry of the well-known writers.

Essentials of Bacteriology: Being a Concise and Systematic Introduction to the Study of Micro-organisms, for the Use of Students and Practitioners. By M. V. Ball, M.D., late Resident Physician German Hospital, Philadelphia, etc. With Seventy-seven Illustrations, some in colors. Pp. 159. Philadelphia: W. B. Saunders. 1891.

This little volume contains a large amount of information condensed within a small compass. It covers the whole subject of bacteriology and is divided into two parts, one dealing with the technique of bacteriological examinations, the other with a description of individual micro-organisms and the various methods of staining and cultivating them. Although the proper pursuit of this fascinating study is practically impossible outside of a regularly equipped laboratory, every practitioner of medicine at the present day should have at least a theoretical knowledge of the subject, which he can readily acquire from a perusal of this book.

The illustrations are clear and satisfactory. In its typography, index, and proof-reading it shows the same careful work as the other compends in the series.

Jahresberichte über die Fortschritte der Anatomie und Physiologie. Herausgegeben von Dr. L. Hermann und Dr. G. Schwalbe. XIX. Band, 1890. I. Abtheilung, Anatomie und Entwickelungsgeschichte. II. Abtheilung Physiologie.

These large and critically edited volumes are invaluable to those who wish to keep pace with the progress in anatomy, embryology, and physiology.

A Text-Book of Physiology. By M. Foster, M.A., M.D., LL.D., F.R.S. Fifth Edition, Revised. Part IV. London and New York: Macmillan & Co. 1891.

This fasciculus contains only the conclusion of the chapters on the nervous system, and the tissues and mechanisms of reproduction; there is also an Appendix on the Chemical Basis of the Human Body. Foster's "Physiology" holds its own as one of the best and most authoritative works on this branch of medical science. If every doctor should read it through once in five years he would be a better practitioner and a wiser man.

An Introduction to the Diseases of Infancy. By J. M. Ballantyne, M.D., F.R.C.P.E. Edinburgh: Oliver & Boyd, Tweeddale Court; London: Simpkin, Marshall, Hamilton, Kent & Co. (Limited). 1891.

A very instructive book founded on a thorough knowledge of the anatomy and physiology of the infant. The author has devoted considerable care in the study of the most important points necessary to the making of a diagnosis in children. This book should be perused by all pædiatrists, and the colored plates carefully studied.

The Prescriber's Pharmacopœia. A Synopsis of the more Recent Remedies, Officinal and Unofficinal, with a Therapeutic Index and a *Résumé* of the British Pharmacopœia Additions, 1890. By a Member of the Pharmaceutical Society of Great Britain. Second Edition. Bombay: Kemp & Co. 1891.

The object of this little work is to furnish information to practitioners of medicine concerning the more recent therapeutic agents about which many of the ordinary text-books are silent. It seems to have been carefully compiled, and the information it gives is, so far as we have been able to compare it, accurate and reliable. It is intended chiefly for Indian practitioners and those living in tropical climates, but it is almost equally serviceable to physicians in other parts of the world. It is a very useful complement to the standard works on materia medica.

Under the Southern Cross. A Guide to the Sanitariums and other Charming Places in the West Indies and Spanish Main. By William F. Hutchinson, A.M., M.D.; Fellow of the American Climatological Society, Member of the American Mecidal Association, Member of the American Public Health Association, etc. Providence: The Ryder & Dearth Co. 1891.

This is a book that really does "fill a long felt want." The visitor to the West Indies has hitherto been obliged to gather his information concerning the places to be visited from ordinary books of travel, written for the most part to please the reader rather than to convey to him any useful information, and containing often most inaccurate and misleading statements. This was for the ordinary tourist, while the health-seeker and his medical adviser had no means whatever of informing themselves as to the climatic conditions, and as to the diseases most likely to be relieved by a sojourn in the islands. Dr. Hutchinson's book gives all this information, and much more, concerning hotels, boatmen, cab hire, etc., and is at the same time a most delightfully written book of travel, which will be read with pleasure by anyone, whether intending to take a trip to the West Indies or only to learn of them from the pages of the author. Physicians also will find it exceedingly useful in helping them to give advice to their patients who must run away from the Northern winters or spring.

Hydatid Disease in its Clinical Aspects. By James Graham, M.A., M.D. Edinburgh and London: Young J. Pentland; Philadelphia: J. B. Lippincott Co. 1891.

This book gives in detail the description of hydatids, their development, growth, and most radical form of treatment. The book is very instructive, and the colored plates very interesting.

Transactions of the Association of American Physicians. Sixth Session, held at Washington, D. C., September 22 to 25, 1891. Volume VI. Pp. 319.

The book in hand contains twenty-three papers by as many of the leading men of the profession. Notable is the one by Dr. Francis Delafield, "On the Disease of the Kidneys, popularly called Bright's Disease," in which he rejects the current classification of kidney disease for one founded on the nature of the morbid process, viz., congestion of the kidney, degeneration of the kidney, and inflammation of the kidney. Under this classification he groups all kidney troubles, giving their symptoms, etiology, and treatment. It is a paper deserving of careful study. Among other subjects discussed are "Tuberculosis" and "Tuberculin" (three papers); "Remote Results of the Removal of the Ovaries and Tubes" (three papers); "Relations between Arterial Disease and Tissue-Changes" (two papers). Other articles are equally worthy of notice, but space forbids.

Doctors in England are complaining that the parsons in the rural districts prescribe for minor ills among the poor, and thus take away patients who could afford to pay small fees.

Dentists in Florida do not need a diploma to practise their profession in that State, so a local court has recently decided.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 5, 1892.

BEVERLEY ROBINSON, M.D., PRESIDENT, PRO TEM.

How to Raise Sunken Noses.—DR. R. F. WEIR presented two patients illustrating rare surgical procedures. The first was a young lady whose nose had sunken from absence of the septum. By making an incision underneath the lip and skin he was enabled to introduce a platinum bridge, which held up the skin while its feet rested on each side of the nasal aperture. Morton had had cases in which the bridge had remained in four years, and Dr. Weir one in which it had remained one year, while in this patient the operation was performed five or six weeks ago. It had been satisfactory in holding up the nose, and had caused no unseemly scarring which other operations involved.

Cranial Gap Filled by Celluloid Plate.—Dr. Weir presented a lad who on November 30, 1891, had sustained a blow on the head, causing a depressed fracture on one side at the junction between the forehead and hairy scalp. After removing the fragments of bone the space left was about an inch and a half by an inch in diameter. The question arose whether to leave this space in an exposed locality unprotected except by the skin, or to replace the fragments of bone, or resort to some other measure. There were three objections to replacing the fragments: 1, They might not unite; 2, if they should unite more or less completely they might subsequently shrink by absorption; 3, in spite of representations of surgeons, he had not been convinced that they would prove entirely innoxious. While the spiculæ would probably become rounded off by absorption, yet since in about twenty per cent. of cases of even simple fractures of the skull epilepsy subsequently developed, there was a basis for some fear of this result after replacing fragments of bone. Finally, he concluded to resort to a method which Fraenkel first practised in experiments upon animals, that is, to fill up the gap left on removing a piece of the skull with a plate of celluloid, and allowing the scalp to heal over it. He would not, however, have resorted to this method on the strength of experiments upon animals alone, but recently had read the report of its application in several instances on man by Professor Billroth. The plate which Dr. Weir used was about one-sixteenth of an inch in thickness. The scalp healed over readily, and the boy had thus far experienced no difficulty.

DR. SHRADY remarked that the case of sunken nose lifted was an interesting reminder of the older method in which a silver plate was used.

DR. WEIR said he had tried to find a record of the silver-plate method, and had gone back in his investigations as far as 1800, but had not succeeded.

DR. SHRADY said he had had occasion to look the subject up five or six years ago, and had found a record of it in an old encyclopædia of surgery. Concerning the covering of the opening in the skull with celluloid plate, it being a foreign body, he would fear that in time it might cause trouble. Perhaps it would become encysted, as bullets were sometimes known to do. He asked whether the plate was not somewhat larger than the opening.

DR. WEIR replied that it was not larger, but was a neat fit for the opening, and rested upon the dura mater. He added another reason for closing the opening, that two cases had been reported in which central nervous trouble seemed to depend upon too large an opening in the skull with disturbance of the circulation, the symptoms disappearing when the gaps were closed.

The Complications and Sequelæ of Tuberculous Lesions Involving the Joints, with a Discussion on the Most Efficient Management of the Same.—DR. V. P. GIBNEY read the paper (see p. 344).

DR. W. T. BULL said he felt under obligations to Dr. Gibney for the manner in which he had brought this subject before the Society. Certain of the features brought out were of special interest to him. One related to the injection of iodoform into abscess cavities, or what had been called, for short, the iodoformization of abscesses. He had not known that any person had practised this to any extent in this country except Senn. Personally he felt somewhat dubious regarding it, especially in joint disease. He did not think Senn's cases had been followed sufficiently long to warrant conclusions as to its safety and value. Dr. Gibney's experience, however, would lead him to try the method when he might meet with such cases in the future.

He could confirm the author's statements regarding the advantage of plaster-of-Paris dressing after osteotomy at the hip, and also as to the value of the Billroth splint. He was pleased to know that he preferred osteotomy below the trochanter minor in osseous deformity following hip joint disease.

He did not think Dr. Gibney had fully shown that it was best for all tubercular disease about the tarsus to heal with, rather than without, suppuration. He was unable, however, to oppose the view by referring to personal experience.

DR. WEIR believed with Dr. Bull that experience with iodoform in abscesses about joints had been too recent to admit of definite conclusions. Experiment in past years had not encouraged him to take up the practice, yet Billroth's results had led him to think the subject over again. He had been interested in that part of the paper relating to compression effects in Pott's disease. He had not supposed that orthopædic treatment alone would give such encouraging results as had been put forth by the author. He believed surgical means had yielded very good results, but unfortunately there was still considerable mortality from that method.

Regarding better results following tuberculosis at the ankle with abscess rather than without abscess, he must say that he had never thought it was a good thing to have an abscess, and he did not think so yet, although he had not had as great an experience as Dr. Gibney. He believed that an abscess connected with the tarsus was regarded by surgeons generally with a good deal of regret, and in his own practice he made it a custom to open as early as possible.

DR. GEORGE F. SHRADY said his experience had been similar to that of Drs. Bull and Weir; that he had been accustomed to look upon an abscess as a calamity, and had made it a custom to shorten the suppurative process as much as possible by opening, scraping, and fixing the joint, etc. Dr. Gibney's experience in the Hospital for Ruptured and Crippled was, however, very extensive and deserved to be duly considered.

DR. BULL inquired of Dr. Gibney whether he drew a contrast between tubercular ostitis of the tarsus in children and in adults. He asked the question because he remembered that a good many years ago Dr. Gibney had written a paper in which he demonstrated that this disease in children would generally run a pretty conservative course if let alone, or treated without surgical measures would terminate satisfactorily. He had generally followed that advice, but when he had interfered in children he had generally had occasion to regret it. A number of operations were likely to have been necessary to bring the case to a termination, or else the patient disappeared from sight during treatment. In tubercular ostitis of the tarsus in adults, occurring in hospital practice, but one case, as far as he could remember, had terminated satisfactorily under a conservative operation. All had gone on to amputation except this one, whose entire foot was removed aside from a part of the os calcis. This man recovered with a useful limb.

Compression Paraplegia.—DR. C. L. DANA said, with regard to compression myelitis, that he quite agreed with Dr. Gibney's views of the treatment. When a case came

under his observation he promptly turned it over to a surgeon for treatment like that outlined by Dr. Gibney, or for operation. He believed surgeons had had some brilliant results from operations in such cases, yet it was only recently that a patient had died of general tuberculosis as a result, he believed, of the operation. That was a possible danger.

He said that while Dr. Gibney had spoken of a compression myelitis in these cases, he thought that clinical and also pathological facts went to show that there practically was not a myelitis; that rather there was simply an obstruction of the circulation, an œdematous infiltration in the cord which interfered with nerve impulse. In connection with this, there probably was also often a pachymeningitis, while in some bad cases there was compression and actual destruction of cord-tissue. But the destruction was a necrotic process, not truly inflammatory. It seemed to him, therefore, that the proper clinical term to apply to the condition was a compression paraplegia, and not a compression myelitis.

Joint Tuberculosis followed by Pulmonary.—Dr. R. W Townsend said that not long ago Mr. Henry Marsh wrote a series of interesting articles by which it appeared that he had traced a large number of cases of joint disease which were followed by pulmonary trouble, perhaps twenty per cent.

Latent Tuberculosis.—Dr. Lyman said that in dogs which had previously been inoculated with tuberculosis, an experimenter had found that in thirty-three per cent. a local tuberculosis in joints could be set up by sprain or injury. It had also been found that in persons who had had tubercular joint disease there were nearly always lesions in the bronchial and mesenteric glands revealed at autopsy. It could not be said, then, that if in a person having a tubercular joint affection pulmonary symptoms should subsequently show themselves that the latter must necessarily be secondary, or that if death took place from pulmonary tuberculosis subsequent to an operation on a joint that the operation was the cause of the fatal issue. These facts, he thought, showed the necessity for not only overcoming the local trouble, but the constitutional trouble as well.

Tuberculin and Latent Tuberculosis.—Dr. Kinnicutt said, *apropos* of the remarks of the last speaker, that when they were treating cases of tuberculosis with tuberculin in the hospitals, it was not uncommon to see tuberculous trouble soon show itself at distant points where previously there had been no evidence of disease. In some instances this took place even within twenty-four hours, so soon, indeed, that it seemed impossible to explain it on any other theory than that the affection was already present, but latent.

Whom to Consult.—Dr. Beverley Robinson said the remarks of the last speakers suggested the question, When was it wise in a case of joint trouble receiving only mechanical treatment to call in an operating surgeon? Might not calling in the latter, who might have a proclivity to use the knife, result in the patient having some latent tubercular foci developed into active inflammation? The question also suggested itself, whether it was best always to excise tubercular glands, or to wait and try general and local treatment other than operative.

Dr. Kinnicutt thought that inflammation was so much more likely to take place in enlarged glands than in joint or bone troubles that one would be justified in interfering surgically much sooner. The fact that they were enlarged showed that a morbid process had already begun, whereas in the case of bones and joints he thought there might be foci of germs without any truly morbid process starting up. He believed pathologists held that the presence of bacilli in fairly large numbers was not of very much importance in itself, it was only when their effect became manifest upon contiguous tissue that danger existed.

Dr. Weir, having been asked with regard to removal of enlarged glands, replied that if the enlargement would not dissipate under ordinary means, and could be got at, it should be removed surgically.

Dr. Gibney, in closing the discussion, said it was true that tubercular joint disease differed in children and adults. Previous to twelve or fifteen years of age an indefinite amount of destruction of soft parts about the ankle and elsewhere might take place and yet the patient go on to have a very useful joint, even though far from any surgeon. An instance was given in the case of a boy who last winter had an abscess about the ankle, opened on about every operation day at the hospital, one abscess forming as another disappeared. After having passed through the winter's torment, the question arose in the summer whether to let him go to a country town, for he still had five or six sinuses and out of the hospital could not receive much treatment. A splint was prepared for him, he went out, had the limb dressed only about once a week, and in the fall all the sinuses had healed and he had a useful foot. There had been no surgical treatment during the summer. He had had so many similar cases that he no longer had any fear about a child's ankle. In the adult it was different, and he agreed with Dr. Bull, that in them the sooner the surgeon went down and took out the foci of disease the better would be the result. In the case of children the worst deformities which he had seen follow disease of the ankles had been in patients who had undergone extensive operations. The best ankles which he had seen in womanhood and which had been diseased during youth or childhood, were those marked with cicatrices. They were not tender nor sensitive, whereas the joint which had not suppurated remained sensitive and liable to strain through life.

With regard to whether there was a compression necrosis of the cord, or a compression myelitis, he could only say that when he attended a course of lectures by Dr. Seguin, some years ago, he spoke of it as a true myelitis. In a great many cases there was nothing more than compression of the cord. If the thickening of the membranes which surgeons found and attributed to an inflammatory process was really due to inflammation, he did not know why the cord itself might not become inflamed by contiguity and continuity.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, February 16, 1892.

A. H. Smith, M.D., Chairman.

The Causation and Treatment of Chronic Diarrhœa was the title of a paper read by Dr. W. W. Van Valzah (see p. 340).

Discussion.—Dr. Andrew H. Smith thought that we were greatly indebted to Dr. Van Valzah for the clear and able manner in which he had discussed the subject, which was a much more intricate one than appeared on the face of it. He thought it would be well to refer, perhaps, to one or two etiological factors which had not been mentioned directly in the paper. One of these was malaria as a cause of chronic diarrhœa. Every now and then a case would occur, and especially in hospital practice, which would baffle all our efforts to control, and yet which would terminate favorably very soon after the adoption of antiperiodic treatment; showing that the real source of the difficulty was of a malarial character. In certain instances the diarrhœa would be the only evidence of the malarial poison in the system.

He agreed with the author of the paper that a large number of the cases of chronic diarrhœa did much better on animal food than on a farinaceous diet. He believed that the reason for this was that rest was secured for the intestines by throwing the work of digestion onto the stomach. He would consider that this was one indication for the use of an animal diet whenever intestinal flatus was present. Sometimes we had a diarrhœa which

was due to imperfect action of the pancreas, and in such cases the administration of ether was indicated.

Dr. Charles E. Lusnily, the Secretary of the Section, said he could add his testimony to the great value of cleaning out the intestines in the treatment of chronic diarrhœa. It was just as useful and as clearly indicated as the adoption of the same plan in acute diarrhœa does to such a source of irritation as green apples, for instance. It had been a good while before he had been able to get himself out of the old rut, having been brought up to consider the use of opiates and astringents as the only proper way of treating these cases; and it required considerable courage at first to give a cathartic to a patient who was having ten or twelve passages from his bowels a day. Of late years, however, he had begun the treatment of all his cases with the administration of a cathartic.

Milk diet was another of the traditions handed down to us in regard to which it had become necessary to modify our views, and personally he had largely given up the use of this. Old-fashioned gruels he had found to be better digested than milk. In the diarrhœa of tuberculous subjects he believed that it was very important for the relief of the pain so frequently complained of, as well as the looseness of the bowels, that the food should be digested before it reached the diseased glands in the intestines. He therefore was in the habit in such cases of giving large doses of pancreatin an hour or an hour and a half after eating, and he had found this practice attended with very good results.

Dr. E. V. Agramonte spoke of the danger likely to arise in the use of milk, especially in summer, from putrid fermentation, which often set in long before there was any evidence of lactic fermentation. The active poison, tyrotoxican might thus be evolved, and cause very serious injury. When milk was used, therefore, unless we could be positively sure of the time that it came from the cow, he believed it was better, as a rule, to employ condensed milk. He also spoke of hemorrhoids as a cause of chronic diarrhœa which, so far as he knew, was not generally recognized.

In closing the discussion, Dr. Van Valzah said that he had not directly mentioned malaria in connection with chronic diarrhœa, but he had meant to include it among the "blood states" of which he had spoken in the paper. The marked effect which the malarial poison had upon the liver, spleen, and blood would naturally lead us to suppose that it might become an important factor in the causation of chronic diarrhœa. In regard to hemorrhoids, whenever proctitis was present in connection with the diarrhœa, hemorrhoids were also apt to be associated with it, both these conditions being usually caused by the frequency of the movements. When there were hemorrhoids, it was invariably his practice to treat them; and, in general, it was always advisable to get rid, as far as possible, of any such source of irritation.

Discussion on Opium Poisoning, Especially from the Medico-legal Side.—The discussion was opened by Dr. Andrew H. Smith, who said that the symptoms were sometimes insufficient for a positive diagnosis. When large doses of opium were taken the stage of excitement was usually very brief. Nausea and vomiting might ensue; the pulse was at first full and strong, but later became thready. The pupils were contracted and insensible to light. The breathing became more and more slow, from the paralyzing influence of the drug on the respiratory centre. Convulsions might perhaps occur, especially in children. The intellect became wholly dormant, but when roused the patient was usually intelligent In a few instances active delirium occurred. The contraction of the pupils was due to the action of opium on the nerve-centres, and not on the terminal nerve-filaments. This was of great value from a diagnostic point of view. The contraction of the pupils was almost invariably symmetrical, but one case was mentioned by Wood in which the pupil of one eye was contracted and of the other dilated. He believed that too much stress should not be laid on the contraction of the pupils. Before death the pupils generally became dilated. Then, too, it was well to remember that the atropia now so frequently associated with morphia in hypodermic injections, tended to produce dilatation.

The respirations, as a rule, were greatly retarded, and as the narcosis became more and more profound, the intervals between them became longer and longer. The paralyzing effect of the drug upon the respiratory centres became so marked that the blood had become very powerfully charged with carbonic acid before they would respond at all to the call for oxygen. The condition of the respiration was generally regarded as the most certain indication of the effects of opium on the system, and in this connection he referred to Dr. Alonzo Clark's directions in the opium treatment of peritonitis, to keep the respirations down to twelve per minute. While, however, it was undoubtedly true, in general, that the slowness of the respiration was an index of the narcotism, cases ending in death were on record in which the respirations were but little, if any, slower than normal. He then mentioned two such cases, one occurring at St. Luke's Hospital, and one at Bellevue. On the other hand, he had seen one instance in which one eighth of a grain of morphia reduced the respirations to thirteen per minute. This was, however, the only symptom of narcotism.

The skin was usually clammy. The pulse became small and frequent; but the change in its character was more tardy than the corresponding change in the respiration.

The diagnosis of opium poisoning was sometimes very difficult, especially in cases where there was no history. In apoplexy, however, the pupils were very rarely equally dilated. Again, in apoplexy, it was not possible to rouse the patient, though reflex movements could be excited; while in opium poisoning the patient could often be temporarily roused, but reflex movements could not be produced. In apoplexy there were often movements of the arm or the leg on one side (the other side of the body being paralyzed); but this was not the case in opium poisoning. In apoplexy there was apt to be strong pulsation of the carotids, but not in opium poisoning. The symptoms of apoplectic effusion in the pons Varolii were said to be identically the same as those of opium poisoning, but it seemed to him difficult to conceive of a lesion situated so exactly in the median line as to produce precisely similar effects on both sides of the body.

In compression of the brain there were usually some evidences of external violence. A patient suffering from alcoholism was apt to babble incoherently, which was not the case in opium-poisoning, and the cold douche was usually effective in dissipating to a marked extent the symptoms of alcoholic intoxication. It was to be remembered, however, that when alcoholics attempted to commit suicide they usually selected opium for the purpose. In many cases of opium-poisoning the odor of the drug could be detected in the breath and in matters vomited.

In uræmic coma the presence of albumin and casts in the urine would usually establish the true nature of the case. To what extent renal inadequacy might intensify the action of opium was a question of interest. There was not the same elimination as in health, and a very moderate quantity of the drug was sometimes attended with fatal results under these circumstances. He had known fifty drops of McMunn's elixir (equal to one-sixth of a grain of sulphate of morphia) to produce death in twenty-two hours, notwithstanding the most energetic efforts to save the patient. The urine was found to contain albumin. In another case that he had seen an ordinary dose of morphia given after a surgical operation was followed by death, and at the autopsy granular kidney was found.

Then, again, the matter of idiosyncrasy had to be taken into consideration. In the case that he had already mentioned one-eighth of a grain of morphia reduced the respirations to thirteen to the minute, and in

another which he had seen a very small quantity of the drug had produced the most alarming symptoms. For the relief of pain a lady had soaked lint in Magendie's solution and placed it on the abdomen, covering it with a hot poultice. In consequence of absorption of the morphia through the skin the respirations fell to five in three minutes, and she became cyanotic and unconscious, but could be easily roused. In this instance oxygen gas was used with excellent effect.

The post-mortem appearances after opium-poisoning were, for the most part, negative. Very seldom was any of the drug found in the stomach if it had been taken in liquid form. If it was in solid form some of it might be found. The lungs and heart generally presented a normal appearance, but sometimes the lungs were congested and the right side of the heart engorged. As a rule, the vessels of the brain were somewhat congested, but in some instances this was not the case. It was to be borne in mind that this cerebral congestion might have resulted from some other cause. The autopsy, therefore, would throw but little light unless the presence of the poison could be shown by chemical tests.

Dr. Van Valzah said he had seen a case of tobacco-poisoning in which the pupils were contracted in precisely the same manner as by opium. The presence of tobacco in the mouth attracted his attention, and on emptying the contents of the stomach a considerable quantity of tobacco was found in them. Under the use of zinc the patient made a prompt recovery.

Dr. P. Brynberg Porter mentioned the case of a young lady in the last stages of diabetes, in whom the administration of a small dose of morphia hypodermically for the relief of pain was followed by profound coma which ended in death within a few hours. The morphia, he thought, had only slightly hastened the impending catastrophe. The coma differed from that of opium-poisoning in that at no time was it possible to rouse the patient to the slightest degree of consciousness. The respirations, too, while rather slow, were not sufficiently so to have indicated danger in an ordinary case of opium narcotism; nor were the pupils contracted to a degree that would ordinarily mark such narcotism.

The Chairman, Dr. A. A. Smith, said it had fallen to his lot to have seen a considerable number of cases of opium-poisoning. He had been somewhat surprised to hear of the case mentioned by Dr. Andrew H. Smith, in which the respirations became reduced to only five in three minutes, notwithstanding which the patient recovered. Some twenty years ago, when he was an interne of Bellevue Hospital, he had seen a case in which the respirations were down to two per minute, and the patient recovered. This case had been reported, and he considered it quite remarkable. About the same time he had seen another case in regard to which there might well have been a mistake in diagnosis. The patient died with all the evidences of opium-poisoning, and at the autopsy a clot was found in the pons, situated directly in the centre, and nearly half an inch in length. It was the only case of the kind that he had ever met with, and he regretted that he had not preserved the notes of it. He remembered, however, that the respiration was of a stertorous character. Within two or three weeks after this last case he was called to see a patient in one of the wards at Bellevue, who had been an inmate of the hospital for quite a long time, suffering from rheumatic gout, and who had been given one-sixth of a grain of morphia for the relief of pain. Profound coma resulted from this, and, notwithstanding the most energetic treatment, he died at the end of thirty six hours. The autopsy revealed a cirrhotic kidney, and he afterward learned that albumin had been found in the urine a month before. In this instance the pupils were markedly contracted, and the respirations were nine per minute. This was one of those cases met with from time to time in which opium produced disastrous results owing to the presence of kidney disease.

There were two other points to which he said he would like to call attention. The first was that in doubtful cases it was highly desirable that the urine should be examined for the presence of opium. This could be done quite easily, and it afforded an important aid to diagnosis. The second was in regard to contraction of the pupils. He had seen this present in cases of alcoholism where there was pachymeningitis on both sides and extending pretty well forward.

Correspondence.

THE HEALTH RESORTS ON THE RIVIERA.

(Continued from p. 306.)

III.—Cannes.

(From our Special Commissioner.)

CANNES IS ENGLISH—HYGIENIC WORKS—THE CLIMATE OF CANNES—AQUEDUCT—PREVAILING DISEASES AND THE QUESTION OF TYPHOID FEVER—THE GRAND HOTEL CALIFORNIE—THE PHYSICIANS OF CANNES—WINTER SEA-BATHING—A STUDY OF VITAL STATISTICS—PRESENT METHOD OF DRAINAGE—THE NEW SYSTEM OF SEWAGE DISPOSAL—INDICATIONS AND CONTRA-INDICATIONS—OUT-DOOR LIFE AND AMUSEMENTS—WALKING BETWEEN NICE AND CANNES—THE REUNION CLUB—THE NEW GOLD CLUB—THE NEW CASINO—BEAUTIFUL GARDENS AND RARE FLOWERS.

Cannes is about five hours by rail from Marseilles, It is really some forty minutes nearer to Paris than Nice, but having selected the latter place as my headquarters it seemed excusable to reverse the natural sequence of localities by first describing Nice. Moreover, Americans have generally preferred Nice to Cannes, and in my humble opinion Uncle Sam comes first.

I have dubbed this settlement the "Little England of Provence," for it is readily apparent that, in spite of her cosmopolitan pretensions, the Cannes of to day bears everywhere the indelible imprint of British life and manners.

Far from being a reproach to the city, this peculiarly English complexion constitutes, perhaps, her strongest claim on the attention of the *fin de siècle* health pilgrim. But real invalids of the old school, especially if they have already reached the uninteresting stage of utter helplessness, ought to go elsewhere in search of a winter sanitarium.

The native Cannois and the numerous band of British colonists are ever ready to extend a hospitable welcome to the visitor. But you are expected to live at Cannes, and not to die there.

It would be considered very bad form by the Committee of Censorious Cannes Dowagers to effect your demise within the limits of their territory. New arrivals will take the hint accordingly. To "see Cannes and die" will never do. But to see it and live, as long as you please, is permissible. And, indeed, life there extends numerous inducements to postpone the final relinquishment.

It is no exaggeration to say that many a despairing dyspeptic, many a hectic expectorator, many a confirmed insomniac has found at Cannes the solace that he never more had hoped to make his own on the better known side of eternity.

But, as already stated, Cannes is British, and probably will remain so. And why not? Did not an Englishman actually discover the new Cannes? Did not English money build her first fine villas, and build them after the English pattern? Are not her fairest gardens laid out on British ideas? And was it not one of England's most famous railroad men, Sir Edward Watkin, who gave the first strong impetus to that series of much-needed sanitary improvements which, when completed, will have fairly revolutionized the old town?

There is no doubt that the hygienic measures already inaugurated will, if carried to a successful issue, make Cannes a very well drained city. The new plans include

the construction of a closed aqueduct for the supply of purer drinking-water, a modern electric light plant, better paved streets, and other works calculated to enhance the value of her natural advantages. No other Riviera resort will then excel, and few will equal, Cannes from a strictly sanitary point of view. Add to this the provision of wholesome amusement, which an enlightened municipality perceives the necessity of supplying, remember her scarcely-dwindling prestige as a centre of exclusive fashion, and Cannes must inevitably grow in public favor. The rather severely select British villa-residents will doubtless resent the further encroachments of a great and promiscuous public; but the native Cannois will hail with delight the dawn of a new era of prosperity. Once more the masses are destined to triumph over the classes. Naturally the sanitary works now in course of construction, and kindred matters relating to public health, specially engaged my attention during my recent stay at Cannes. The same willingness to extend every possible facility for personal inspection and study, already favorably commented on in connection with Nice, was also displayed by the authorities at Cannes. The Mayor himself, in company with the Engineer in-Chief, the British Vice-Consul, and other dignitaries, conducted me to every point likely to prove interesting or instructive.

Drs. Frank and de Valcourt (the latter the United States Consular agent) also gave me much of their valuable time and assistance in these tours of investigation. Many maps and plans were specially prepared for the Medical Record Commissioner by M. Ferrand, of Paris, who is the engineer in full charge of the works of construction. It must be considered fortunate for the future welfare of Cannes that her present municipal authorities are so fully alive to the necessity of conforming to Anglo-American standards of efficacy in matters of drainage and domestic hygiene.

The work already finished was carefully examined by me and is an earnest that everything will be well done. The importance of this point is not to be underestimated, for it is an open secret that the Riviera boasts of certain improvements that do not improve, just as there is a dangerous class of individuals who always "positively know" things that are not so.

On the peculiarly favorable climatic conditions of every Riviera station local enthusiasts have written voluminous verbiage. Common sense will steer one clear of all this tangling mass of weedy chaff.

The Riviera climate is, in general, stimulating, warm, and dry. Plenty of exhilarating sunshine and plenty of puffy wind are its chief characteristics. Sudden and rather violent changes in temperature are an almost daily occurrence. One spot may be a little more sheltered than another, one may be a little more inland than the next, one may even average up several degrees warmer than the preceding one. But all these hair-splitting distinctions make no essential difference.

When you have waded through a bewildering lot of statistical records, when you have painfully pored over a multitude of tables covering every conceivable meteorological detail, such as barometrical, thermometrical, actinometrical, pluviometrical, psychometrical, anemometrical, and what-not-metrical observations—when you have conscientously performed this trying task, the only tangible result is that it has made your head swim, and what may be left of your brains reel. For the speedy development of hardened climatic cranks a course of Riviera health-resort literature may be confidently recommended.

The climate of Cannes is a Riviera climate. *Voilà tout.*

Cannes is not outside Provence. And of all Provence it has been well said that there is little level land in the department. One range of hills rises beyond and behind the other: first the wooded hillocks, where the hyacinths lurk; then the slopes, so gay with heath and myrtle and arbutus and prickly broom, next the bare limestone ledges, and last of all the peaks where the snow-wreaths and glaciers hang, and which, as they meet the clouds, assume the hues and imitate all the aspects of cloudland. This description fits Cannes, as it would fit Nice or Hyères, or almost any of the winter stations along the French Riviera.

The mistral blows at Cannes when it listeth, in spite of all alleged protecting mountains. To the uninitiated "mistral student" it is rather perplexing to learn from local Riviera authorities that this blighting wind touches with terror every point along the littoral, except their own particular place. Such purely local exemption is again quite unknown outside the narrow limits of the particular resort in question. As a matter of fact, it may be safely stated, on unbiased outside testimony, that the mistral gently blows its dusty breath wherever it suits His Windy Majesty to do so.

Your geography will show you that the Rhone valley somewhat resembles a funnel, collecting the cold air from the north and concentrating it upon the overheated southern shorelands. There you have your mistral. Forego teasing your brains with more complicated explanations. The mistral may not mind it, but you probably would. One who evidently knows thus compliments the wind that lingers long in all Provencal narratives: "There used to be an old saying that

> Parliament, Mistral, and Durance
> Were the three scourges of Provence,

and no doubt the third day of a howling mistral is a trial to most people. The cypress hedges are bent down almost to the earth, which they are unable to protect; every window shakes, and all night long, across every bar and through every keyhole, this wild wind discourses. Its medley of raving, whining, and bellowing is very annoying, and as for the dust that is everywhere! It is in your eyes and in your hair, in your dress, in your ink-bottle, and between the leaves of your books. Meantime your pens split (goose-quills), your shutters crack, your hat flies away, and your hair turns gray; but your spirits are unaccountably buoyant, and the sky, from side to side, is of the palest blue. The sea, on the other hand, looks dark; there is a fringe of surf round the shore; the horizon line is a broken one, and the water is of every shade imaginable, from a deep hyacinth-like purple to a greenish turquoise. This much-abused mistral has been christened by the knowing peasantry '*lou bon vent.*' It is really a public benefactor, for this 'prince of the power' of the air clears the country from damp and miasma, and is, therefore, one of the great sanitary features of the seaboard."

But besides the mistral there is a choice assortment of other winds at Cannes, as well as elsewhere along the Riviera. They are not inexperienced spring zephyrs either, but able-bodied, whole-souled fellows, who have long since attained their majority.

There is that rather frolicsome south-southeast breeze, called the *sirocco*. Connoisseurs like it dry, but usually get it dampish. It comes over from Africa, and when you have finished wrestling with it you are generally in a mood to concede its open virtues.

Then you have the *greco*. He is a wayback northerner of brazen cheek. He discovers you in hiding and unceremoniously presses his claims to immediate recognition upon you. Nevertheless, he is a cold one, and when he leaves, you wish him godspeed and forget to add "au revoir." In the heat of summer he loses his vim and degenerates into a mere land breeze, springing up every evening and lazily lulling seaward.

The *tramontano* is a pure-bred "nor'easter." When he condescends to climb over the protecting range of mountains, he is rewarded for his pains by getting the cold shoulder from everybody. This base ingratitude makes him rather coy, and he is but a rare visitor in these southern lands.

The above are the main attractions of the Riviera in the wind line. There are yet a few side-shows. But of these only the *vent Est* (*levante*), with nothing characteristic about it except its weak blow, and the *vent Sud-Est*

(*marin*) require mention. The latter is a Genoese foreigner of tediously rainy proclivities.

But enough of wind and winds. Let us try something more substantial. Water might do to start it on, though prohibition in France is not very popular.

The drinking-water now supplied to the residents of Cannes is by no means what it should be. To begin with, its very source is not above suspicion. A mountain stream, La Siagne, is tapped at the little village of St. Césaire, two hundred and thirty-five metres above the level of the sea, and then for miles an open canal carries the water to certain reservoirs. The latter serve as tanks for its final distribution.

The intermediate process of filtration may help to separate some of the grosser inorganic impurities of the water, but there is no kind of safeguard against possible organic contamination. Even pollution by sewage may happen along the course of this canal. The Cannes drinking water should, therefore, be thoroughly boiled before being taken.

It is satisfactory to know, however, that the plans for a new closed aqueduct are already in the hands of the Mayor. Work is to be begun this spring, and pushed forward with all possible speed. The authorities should not omit to exercise due vigilance in securing an unimpeachable source of supply. River water is not desirable. They ought surely to succeed in finding something very much better than the Siagne stream. Tap a mountain, but do not suck a river dry when you want pure drinking-water.

Mr. Ginner, who has kindly supplied the analysis states: "It is, however, my duty to say that on another occasion I found more than this. But even then it did not reach the maximum beyond which good water should never pass; and further, the analysis was performed soon after or during the heavy autumn rains, while the cistern from which the sample was taken, although at the time supposed to be in a fairly good sanitary condition, was afterward found not to have been so.

"Some five- or six and-twenty years ago, nearly all the important water supplies of France were examined for comparison. I believe I am correct in stating that the Cannes water came out third on the list of purity and excellence.

"My own experience and that of my colleague, M. Tajasque, lead us to think this high degree of quality is still maintained."

The opinion of these gentlemen is, of course, entitled to consideration. But the fact remains that the Cannes drinking-water is carried to the town in open canals, and what that means every physician knows. The water may be safe to-day and highly dangerous to health and life to morrow. Open canal water should be invariably boiled before being taken. No exception can be made in favor of Cannes, no matter what the authorities may say.

There are no wells at Cannes whose polluted waters could poison unsuspecting travellers. But even well-water could scarcely be more unsafe than the river-water now supplied for domestic purposes.

Barring the ubiquitous and deadly influenza, I was unable to discover any prevailing disorders at Cannes. A study of mortality also shows this absence of endemic maladies. Still, it is not denied that people are apt to catch severe colds at Cannes; that sensitive throats and noses are sometimes made much worse there; and that the irritating dust may prove troublesome to weakened eyes and lids. Many of the streets are poorly, or not at all, paved, and dust is everywhere. When it rains the dust puts in its fine work as tenacious mud. As for typhoid fever, Cannes has been quite unjustly made to shoulder the blame for some imported cases, the number of which has, in addition, been greatly magnified by certain well-meaning neighbors of mildly envious disposition. Such things happen at popular summer resorts. Why should they be foreign to competing winter stations?

Here are the facts. In the year 1881 Cannes was visited by an outbreak of typhoid fever. There were large works going on at the time. One land company alone employed some five thousand Piedmontese laborers. The disease, encouraged by the filthy habits of these ditch-sleeping workmen, spread to the better sections of Cannes. In the Anglo-American colony about twenty cases occurred. There were also some deaths. Yet since that time only sporadic cases have appeared. A grandson of Sir Edward Watkin was prostrated with the disease at the Hotel Californie in 1889. This case, although not terminating fatally, gave rise to a great deal of adverse comment. A thorough overhauling of the Californie, as well as other hotels, was one beneficial consequence of the agitation which followed.

To show the wretched condition of things then existing, it is only necessary to quote a few lines from the official report forwarded to me at the request of Sir Edward Watkin, by Mr. Fred C. Lynde, the well-known sanitary engineer of Manchester. Among other things Mr. Lynde says: "On arriving at the Cannes Railway Station, a most disgusting smell arises from the open drain passing near to."

In regard to the Grand Hotel Californie, as it was in February, 1889, the following quotation speaks for itself:

"The defects mentioned in this report may be summarized as follows: The smell arising from the putrid animal and vegetable matter deposited near to the hotel; the foul condition of the bed of the stream, situated on each side of the garden; the evils arising from the large unventilated cesspool, situated under the tennis court, by the escape of foul gas therefrom; the escape of noxious gas into the hotel through the defective water-closets and connections; the danger arising from the unused water-closet on the ground floor, which must render the atmosphere of the hotel very vitiated during the night, when all outside doors and windows are closed; the leakage of gas from the defective joints of the soil-pipe at the west end of the building, which emits gas near to the windows; the ventilation pipes, terminating close to the windows, thereby discharging foul gas into the building; the soil-pipe of the water-closets at the east end of the building being in a leaking condition, and terminating with an open end within the roof of the hotel, thus discharging gas into the roof; the excessive size of the soil-pipes; the drains being situated under the kitchen floor, and terminating in obsolete traps; the waste-pipes not being properly disconnected from the drains in some instances, nor trapped in an effectual manner; the ventilating grids connected with the soil-pipes terminating in the main walls of the building; the filter being a possible source of contamination to the water; the housemaids' slop-sinks allowing the slops to overflow; accumulation of water and grease under the hydraulic lift; accumulation of manure-water at the back and side of the stable and near to the hotel.

"Under the above statement of facts, which I have carefully verified as far as possible, and which cannot in any sense be controverted, my opinion is that the hotel is not in a sanitary condition."

As an illustration of the good accomplished by Sir Edward's energetic efforts, it may be mentioned that on a thorough inspection of the hotel in question, I found that, excepting some insignificant details, every one of these grave defects had been thoroughly remedied. It is true, the method of filtration of the drinking water is not preventive of possible infection. But in a general way the hotel may now be considered safe and sanitary. In particular the dangerous cesspool, situated under the tennis court, has been entirely cut off, and is now empty. The system of drainage is perfect, having been constructed under the personal supervision of Mr. Russell, of Cannes, the able representative of the London firm of Best & Co.

It seems advisable, in this connection, to explain the truly great importance of the typhoid fever question, as well as zymotic disease in general, to foreign visitors at any given health resort.

When the stranger makes anxious inquiries concerning this point, he is usually put off with the statement that everything is all right. For, he is told, the natives have lived in such and such a locality, they have taken the local water, they have lived in sewage-contaminated dwellings from time immemorial without detriment to their health. Right here you have the solution of the whole problem. Accustomed from infancy to all sorts of impurities, the native population is fully protected by an involuntary course of repeated inoculation with attenu ated poisons. But a foreigner is not thus protected.

The very thing that has conferred immunity on the native, may easily cause the speedy death of the foreigner. It is the old story of what is one man's meat being another man's poison. And now let the natives cease their futile attempts to throw ridicule on over-anxious foreigners. The stranger is right every time, and the local enthusiast is just as often wrong. He may sneer at the timidity and alleged ignorance of the newcomer. But the sneer shows only his hopeless stupidity or criminal malevolence.

(To be continued.)

OBSTETRICAL SCIENCE AND ARCHITECTURE.

To the Editor of the Medical Record.

Sir: In the article entitled "Obstetrical Science and Architecture," which appeared in the last number of your journal, I find a misstatement with reference to the Sloane Maternity Hospital. The article states that there were 3 deaths in 1,000 consecutive cases delivered in this hospital, whereas, really, there were 6 deaths in the first 1,000 cases and 5 deaths in the last 800 cases, making a total of 11 deaths in 1,800 consecutive cases.

A brief explanation of these 11 fatal cases may be of interest: One death was due to rupture of the uterus and ante-partum hemorrhage. This patient was brought in by ambulance after being in labor for three days, during which time she had bled profusely. She died twenty minutes after admission, completely exsanguinated. Autopsy revealed a ruptured uterus. Two deaths were due to placenta prævia. One of these, an ambulance case, was moribund on admission. The other was a case of premature labor, with central implantation of the placenta; death was due to hemorrhage, most of which occurred before delivery could be accomplished. One death was due to chronic Bright's disease, not to labor. One death was due to eclampsia, after eighteen convulsions. One death was due to septicæmia. This patient was admitted in the second stage of labor, in a most filthy condition; she had been attended by a midwife, and was undoubtedly infected before she entered the hospital.

Of the 5 deaths in the last 800 cases, 2 were due to eclampsia. Both of these were moribund when brought to the hospital. One death was due to exhaustion and necrosis of uterus. This patient was brought in after having been in labor for five days, and after several attempts had been made to deliver with forceps a full-term head through a pelvis whose true conjugate at the brim measured 6.8 ctm.; autopsy showed an area of necrosis where head had pressed the uterus against the sacral promontory. One death was due to chronic Bright's disease and alcoholism; this patient had been on a two weeks' debauch and was delirious when admitted in labor; soon after delivery she sank into coma and died. One death was due to pneumonia (from prolonged exposure to cold), contracted before admission to hospital.

An analysis of these cases shows that five were moribund on admission; that three died from causes outside of the department of obstetrics; and that the only fatal case of septicæmia which has occurred here originated outside of the hospital.

Considering that over one-half of all our cases are admitted already in labor; that many students and pupil-nurses have the privilege of making examinations per vaginam; and that often "desperate cases" are sent in after midwives or physicians have failed to deliver, I think that the statistics of this hospital will compare favorably with other statistics in the same line.

"Architecture and elaborate appliances" may not be "absolutely essential to successful work," but they are certainly an important factor in obtaining the best results, and in the course of time they will aid in raising the already high standard of modern obstetrics.

LEPROSY AND A FISH DIET.

To the Editor of the Medical Record.

Sir: Dr. L. Duncan Bulkley, in stating his conclusions as to the non contagiousness of leprosy, says (Medical Record, March 5th):

"4. There is strong reason to suspect that it may first be introduced into the system by the way of food, and fish is the most likely of all substances to furnish and convey the poison."

In his original paper (Medical Record, January 23d), he makes this view even more prominent. I am aware that this theory of Hutchinson's has gained wide acceptance, but it is generally discredited by physicians in Hawaii, for what seems to me a very strong reason.

From time immemorial, the staple food of the native Hawaiians had been fish, and principally raw fish. Until about 1860 there is no history nor tradition of the existence of leprosy among them. At about this date it appeared, and at the time of its appearance, white people had been among them for forty years, and their food and methods of living had changed greatly. Canned foods, fresh meat, and vegetables had been so widely introduced, that the use of fish, and especially raw fish, had been enormously decreased, and could not be considered as a prominent feature of their diet.

At the present day, while consuming no remarkable amount of sea-food, one Kanaka out of every thirty is a leper. All fish, no leprosy; little fish, much leprosy. This has been the history in Hawaii.

Yours very truly,
Augustin A. Crane, M.D.,
Recently Government Physician in Hawaii.

New Instruments.

AN IMPROVED CLOVER'S CRUTCH.

By Frank LeMoyne Hupp, M.D.,
Wheeling, W. Va.,
Late House Surgeon to the Presbyterian Hospital, New York.

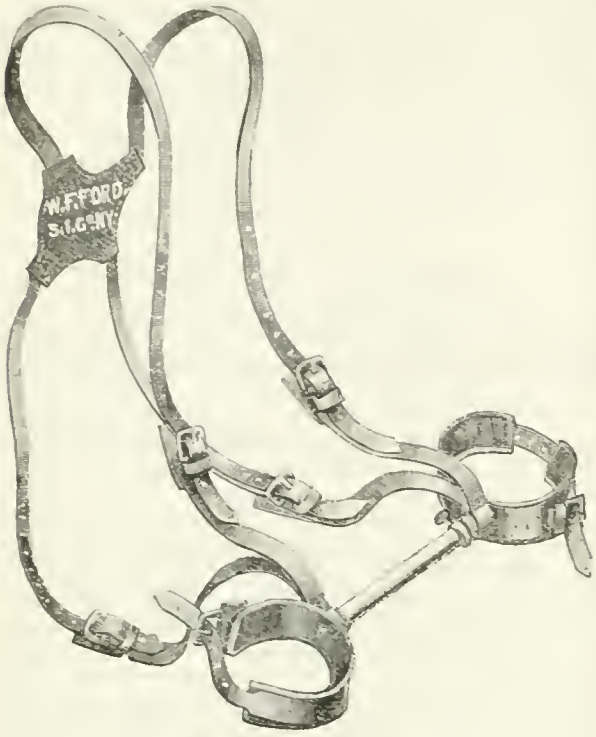
In Volume XXII., December 9, 1882, of the Medical Record, there appears a letter from Dr. George A. Peters on "A Substitute for the Wrist and Ankle Band." This instrument, popularly known as Clover's crutch, is used perhaps in every large hospital in this country for all perineal surgery. While the contrivance is decidedly ingenious and was a vast improvement over the old anklets and wristlets of Pritchard, it has many faults.

After giving ether to upward of fifty patients wearing this crutch and noting at the time of operation the engorged venous trunks of the neck and head, the embarrassed breathing, and subsequently the distressing headaches, I thought an improved instrument might be made.

The accompanying illustration explains itself. The sliding iron rod, the padded leather straps, which buckle around the leg below the knee are the same as those in the instrument introduced by Dr. Peters.

Instead of carrying the padded strap behind the patient's neck the apparatus I wish to suggest as a substitute has a pair of buckles on either side, at the junction of the connecting rod with the leg straps. Attached to

these buckles there are four straps; two coming over the shoulders in the direction and position of suspender straps to be fastened to the two upper buckles; and two com-



ing up from the side of the body to be secured by the two lower buckles.

This instrument has been used for five months in the Presbyterian Hospital, New York, and it is found that it not only does away with the neck pressure, and the distressing symptoms arising therefrom, but the straps of one side antagonize those of the other, thus keeping the patient quietly on his back without any rolling to either side.

This instrument is made by Mr. Ford, of the W. F. Ford, Surgical Instrument Co. It is easily and quickly applied.

1212 Chapline Street.

A DOUBLE NASAL SPRAY AND VAPORIZER.[1]

By J. BLAKE WHITE, M.D.,

PHYSICIAN TO CITY HOSPITAL, BLACKWELL'S ISLAND, NEW YORK.

The value of inhalants, especially in the treatment of chronic catarrhal conditions affecting the air passages, is generally admitted. Everyone who is much in the habit of employing this mode of practice, must have noticed how small a proportion of any medication used appears to attain a distance sufficient within the air-passages to accomplish the good intended.

It was doubtless in the presence of such an experience as I have named that Dr. John T. Gray wrote: "I am confident that, if means could be devised whereby remedial agents could be applied to all the ramifications of the lungs, including terminal cells, a great step would be taken toward the cure of consumption." Such prospect certainly appears beyond all expectation. The vain hope of ever being able to diffuse even the most attenuated vapor, whether medicated or not, to the liberal extent coveted by the learned authority, need never be indulged, since, should even the many resisting sentinels about the throat be passed without a challenge, the antagonism of residual air, ever present in the lungs, would oppose a determined barrier to the free entrance of foreign matter beyond a limit bounded by the elastic property of air. The fact, however, that but a limited quantity of any medicated agent forced into the air-passages by means of an atomizer, rarely exceeds in range beyond the primary bronchi, should never deter us from essaying the method of treatment whenever indicated, as we may confidently expect some aid from force of gravitation to operate subsequently in our behalf, which would diffuse the influence of our remedy after introduction to areas unapproachable by any other process.

Recognizing the fact that the administration of medicaments by inhalation in the ordinary way is invariably opposed by active elements of resistance about and beyond the throat, I have long since abandoned this course of proceeding, and I now desire to lead in the direction of another recourse which promises more satisfactory results.

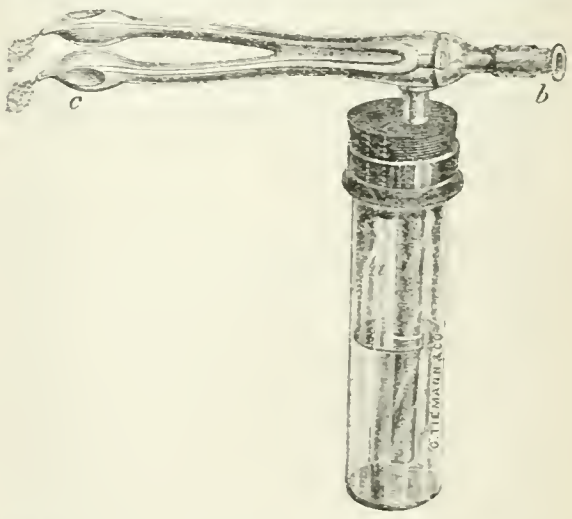
The nasal passage is not only the natural respiratory tract, but the most direct route to the lungs. Its mucous surface is specially adapted to the performance of the vital act of respiration, and its comparative insensitiveness to manipulation seems to single it out as the proper avenue through which to address remedies to the respiratory passages.

Experience commonly demonstrates that medicated agents directed to the air-passages by the mouth excite gagging and even cough, which, when administered through the nostrils, the sensitive fauces having been thus eluded, would give rise to no marked degree of discomfort.

The "Besseler Globe Inhaler," and the "Evans Vaporizer" are indeed excellent additions to the armamentarium of the lung and throat specialist. Their utility, however, is abridged, owing to the necessity the operator is under with their use to apply his medications by way of the mouth.

The vapor to be used, if employed sufficiently rich in medical virtues, is apt to excite great irritation about the fauces, followed by persistent coughing. In addition to this, the very necessary degree of force which is demanded to project the medicament beyond the fauces is apt to occasion involuntary closure of the glottis, and thus to preclude entrance into the lungs of a sufficient proportion of the medicated agents to effect the measure of good required.

In order, therefore, to facilitate my peculiar method of throat and lung medication, I have devised, and I believe perfected, a double-tubed nasal spray atomizer, the model of which I herewith submit. An elaborate description is



wholly unnecessary, as the above woodcut will show its special features of advantage. When attached, as it is intended it should be, to a condenser, the vapor is forced equally and simultaneously through both tubes directly into the nose, aided by a full and deep inspiration.

The admission of a small modicum of atmospheric air is, of course, necessary to promote the entrance of the medicated vapor into the deeper air-passages, and this is provided for by longitudinal grooves about the bulbous extremity of each tube, indicated at the letter *c*.

INTESTINAL ANASTOMOSIS AND SUTURING.

BY ROBERT ABBE, M.D.,

ATTENDING SURGEON TO ST. LUKE'S HOSPITAL; PROFESSOR OF SURGERY TO POST-GRADUATE SCHOOL OF NEW YORK.

THE following cases of recent intestinal surgery form a legitimate basis for practical observations on the comparative merits of various operative measures in this important line of work. There has been so much in recent literature of experimental work upon dogs, from which conclusions have been drawn perhaps too hastily, that recorded cases of practical work may now be considered of the utmost value in drawing legitimate conclusions.

CASE I. *Intractable Fecal Fistula—Resection of Two Inches of the Ileum—Lateral Anastomosis—Recovery.*—C. B——, a fine, large, healthy Swedish girl, twenty-four years of age, was taken, soon after coming to this country, with severe dysmenorrhœal pains, for which she was treated by gynecologists for uterine displacement during a year and a half before she came under the care of Dr. Currier, of this city, who by laparotomy sutured the uterus to the anterior abdominal wall. Relief not being accomplished, both ovaries were removed later. They were in condition of cystic and papillomatous hypertrophy, one being nearly as large as an egg.

A large amount of pus was evacuated from the pelvis three weeks later, and a rubber drainage tube inserted. The discharge was very free, and intestinal contents were found in it after a little while. A long rubber drainage-tube was inserted, but disappeared one day into the abdomen—being sucked in by peristalsis. Dr. Currier again did laparotomy and found the tube in the intestine, some distance from the fistula. He incised the bowel, removed the tube, and sutured the incision. The adjacent adherent bowel was loosened, but the fistula was left for nature to heal. Some weeks later she had arrived at a deplorable state, reduced in flesh and suffering constant pain from the surface of the abdomen, whose skin was excoriated for some inches about the fistula. On examination a fistulous opening was seen in the median laparotomy scar—less than two inches above the pubis. This admitted the index-finger to pass its entire length into the bowel. Through the opening there was a constant flow of turbid intestinal fluid, sometimes containing bile, and after eating, bringing up with it considerable portions of partly digested food. The peristalsis caused an intermittent welling out of this acrid secretion, which had digested the superficial layer of the skin of the abdomen, so as to produce a red, excoriated, and extremely painful surface over the entire lower abdomen. Ordinary strapping and plugging were ineffectual in holding back the fluid. This condition added misery to the patient's increasing emaciation, and led her to despair.

The nature of the secretion left no doubt that the portion of destroyed intestine was high up in the ileum. The injury had apparently taken place during separation of adherent bowel at the former operation, and a portion had sloughed.

A few days were allowed for the excoriation of the abdomen to heal, by plugging effectually with a section of rubber ball, to the centre of which a string was attached, and fastened to a roll of gauze laid on the abdomen across the fistula, while the rubber pad was slipped into the bowel and drawn tightly up against its inner surface. This method I have found most effectual in closing fecal fistulæ temporarily. It worked well here, and in a few days the abdomen was nearly healed. One day it was tied too loosely and peristalsis swept it quickly into the bowel, and it could not be withdrawn, until at operation it was found nearly a foot away and drawn back by the string, which was caught at the wound.

On May 29, 1891, I did a laparotomy and found a loop of small intestine, quite high up, bound tightly to the abdominal wall around the fistula, and to neighboring intestine also. Careful dissection showed that two-thirds of the lumen of the gut at the site of the fistula had been destroyed, and resection was the only resort to restore it. I therefore dissected the entire mass of adherent bowel from the abdominal wall and from the bladder, to which it was intimately adherent, so that in the dissection a small opening was torn into the latter. This I immediately sewed up and tested by forcing Thiersch's solution into the bladder to prove its perfect closure.

The matted bowels were then separated from each other. In doing so I found a silk pedicle ligature at the site of one ovary, with some drop or two of pus about it. This I cleaned away. Two inches of the injured gut were then resected, including the fistula. Each severed end was inverted and closed by a double row of continuous fine black silk suture. The mesentery having been sufficiently divided, there was no trouble in drawing the ends past each other so as to overlap for six inches. In this position they were sutured together by a double row of continuous silk suture, and an incision four inches long made in each opposing bowel; a quick overhand, running suture of the cut edges, and the continuation of the double row of sutures about the opening completed the anastomosis. The parts were now washed with boiled water and replaced. The abdomen was closed without drainage. Primary union occurred. Convalescence was uninterrupted. The temperature remained below 100° F. A seidlitz powder was given daily after the second day. On the third a large movement occurred, repeated daily. Her appetite became enormous, and flesh was rapidly gained.

She is now in perfect health and the abdominal scar is strong. (The patient was exhibited.)

CASE II. *Double Intestinal Obstruction—Resection of Cancer of Sigmoid Flexure—Lateral Anastomosis—Complete Recovery.*—Miss E. R——, aged forty-one, was referred to me, April 5, 1891, by Dr. W. H. Draper, with the following history of obstruction: Ten days previously she had observed increasing constipation, and began to take physic without effect for four days, when her physician was called, who, after exhausting all expedients without more effect than emptying the lower bowel of scybali, diagnosed obstruction requiring surgical interference. She was unable to void flatus per anum, but had considerable in the intestine. She had little abdominal pain. Four days previous to her admission to St. Luke's Hospital she had stercoraceous vomiting, as reported by her physician, which was repeated on the following day.

Examination showed a distended abdomen with some tympanites, though dull in the right half and across the upper abdomen. No certain indication could be found of the seat of obstruction. After consultation I decided to explore the left ileo-hypogastric region through an incision as for inguinal colotomy, and make a temporary relief if found desirable, inasmuch as she was not in good

condition to do any extensive surgical procedure. I was surprised to find the descending colon empty, and the ascending and transverse colon enormously distended. The distention terminated in an abrupt rounded bowel in the left hypochondrium. Without searching for the cause of the obstruction under these difficulties, I decided to make a temporary right inguinal colotomy and stitch the caput coli in the wound. This I did, and on the following day opened the caput coli and evacuated a great accumulation. She made a quick convalescence, and on the ninth day I did a laparotomy on the outer side of the left rectus, at its upper part, in order to relieve the supposed obstruction of the splenic flexure of the colon found previously. On reaching the colon it was found sound and empty from the caput coli to the sigmoid flexure. Search for the cause of obstruction revealed an anomalous double meso-colon from the splenic flexure downward, a finger's-length on the outer side of the normal one, forming at its lower edge an inverted pocket into which the colon had formed a hernia, which had been spontaneously corrected after the bowel had been evacuated by colotomy. This, it was thought, had completely explained the former trouble, and the abdomen was closed. Subsequent efforts, however, failed to bring fecal evacuations from the colotomy wound to the rectum, nor would colored fluid injections find their way in the opposite direction. The distended rectum could be made to hold but a small pint. No tumor could be felt by palpation.

May 13, 1891.—She was again subjected to search of the left iliac region through a wound on outer side of the rectus, low down. The empty descending colon was traced down to a very small, knotty cylindrical stricture of malignant origin, which was found, on distending the rectum, to allow no fluid to pass. It was located twelve inches above the anus. Resection of this, and three-quarters of an inch of sound bowel on either end, with a portion of the mesentery adjacent, was done with considerable hemorrhage, readily controlled. The ends of the divided bowel were completely closed by continuous suture, and the two free parts overlapped to their utmost, which proved to be four inches. After suturing them in position, opposing incisions were made in the bowel three inches long. This was carefully measured in view of future estimate of stenosis. The anastomosis was quickly completed and the cleansed parts dropped back. The time of the anastomosis was forty minutes, but inasmuch as the entire operation, including search, separation of old adhesions, resection, etc., with concluding closure of the abdominal wall, occupied over three hours, I am free to confess that, to my mind, it makes little or no difference whether the time given to the act of uniting the bowel was thirty minutes or forty. It was in this case much more important that the union should be absolutely perfect. The use of artificial rings and plates was in my mind throughout the operation, and I had several sizes and varieties prepared and at hand, and could but feel that I would not only have been hampered at every step of suturing around them, but would have been wholly uncertain of exact apposition by any method other than the simple suturing, which worked like a charm in this case, for the parts could not be brought out of the wound. The patient endured the operation very well. On each day she passed flatus. On the second day the colotomy wound was plugged. On the third day a large-formed movement passed per rectum, and from that day her convalescence was uninterrupted. Daily evacuations occurred, either from medicine or naturally. The colotomy wound closed to a sinus which leaked a little, but was perfectly controlled by a strap.

During the summer she got back her flesh and health, and continued to have normal movements, enjoying a happy summer in the country. Six months after operation she came to me, looking in perfect health, but complaining of fulness in the pelvis. Examination revealed a small growth of the right ovary, the side opposite to the diseased sigmoid. In one month this had undergone a very rapid growth and was as large as a child's head. For my accommodation, Dr. Robert F. Weir very kindly took the patient into the New York Hospital and removed a large carcinomatous right ovary, which had formed many adhesions, and grown intimately to neighboring parts; but she did not recover.

I had the satisfaction of examining the anastomosed parts of the colon *in situ* during this operation, and found absolute freedom from cancer anywhere about that side of the abdomen, except a speck of suspicious growth, the size of a mustard-seed, in the wall of the bowel, two inches above the anastomosis. This specimen, removed from the patient after death, and prepared by Dr. Ferguson, pathologist of the New York Hospital, I have the satisfaction of showing you now. The restoration of the lumen of the bowel is perfect.

The oval aperture between the two portions is, as you see, large enough to admit two fingers side by side up to the first joint, and ably demonstrates the perfect union and freedom of a proper channel produced thereby of a lateral anastomosis by suture.

With regard to the possibility of an end-to-end suture of the bowel in this case, I would say that I had here to deal with bowel of two unequal diameters, as happens so commonly in stricture with dilatation above it; and after resection of the diseased part and its infiltrated mesentery I feared to unite the ill-matched ends.

Case III. *Intestinal Obstruction from Incarcerated Hernia—Resection—Lateral Anastomosis — Recovery.*—P——, aged thirty five, Plattsburg. Five years ago was caught between two cars and sustained a crush of the body that caused a traumatic hernia of the abdominal wall, just below the ribs, on the outer side of the left rectus muscle. This hernial tumor was as large as a flattened goose egg, and gave him no serious trouble. Three weeks ago he had an injury of the part by the thrust of a stick, and began to have symptoms of obstruction—loss of appetite, some vomiting, pain in the upper part of the abdomen but not in the hernia, constipation, loss of flesh, and jaundice.

Examination showed a flaccid hernial mass at the side described, and some dulness of the hypochondrium.

December 28, 1891, I operated, making first a median incision above the navel to introduce two fingers for exploration. The fingers entered a sharp-edged hernial pouch, two inches in vertical diameter at the site mentioned, to the edges of which omentum was adherent. A vertical incision was now made directly over the hernia, and a loop of small intestine found embedded by firm old adhesions in the tissues of the abdominal wall. This was with much difficulty dissected out; at its upper part it was so matted to the sharp edge of the ring that a rent occurred during its removal. Its complete removal being accomplished, and sound intestine being drawn out of the abdomen, it was found that the intestine, under pressure, where the rent occurred, was atrophied to a fibrous tube, the size of one's little finger, for an inch and a half, and without a mesentery to nourish it. The intestine above it was the jejunum, thickened and distended by chronic obstruction. The damaged portion, about an inch and a half, was therefore resected, and the ends of the sound gut sutured. Protecting the abdominal cavity, and drawing the two adjacent portions of sound intestine out of the abdomen, they proved to be of wholly unequal size and not adapted to end-to end anastomosis. I therefore laid their two ends together and did a lateral anastomosis, after the manner followed in other cases, using sutures only of fine black silk around an incision of full four inches in each bowel. The entire anastomosis occupied thirty-six minutes, and was most satisfactory. The parts were washed in hot water and replaced, and the abdominal wounds closed without drainage. Uninterrupted convalescence occurred. The bowels moved by enema on the third day, and afterward by salines. The sulphate of magnesia, a drachm, repeated once or twice.

To-night, the fourteenth day, the man presents himself for your inspection in restored health. The jaundice disappeared directly after operation, and I can only explain it by believing the over-distended duodenum allowed the bile to be retained

Case IV. *Resection of Six Inches of the Rectum by Kraske's Method — Circular Suture — Recovery.* — M. K——, aged twenty-nine. One year and a half ago this patient began to notice growing constipation, requiring medicine. Later she had occasional colicky pains in the abdomen, with nausea and vomiting, progressive weakness, with bowel relief only in watery movements through medicine, and increasing nausea led her to seek advice.

February 14, 1891, when I first saw her, she had had no movement for a month. She was in a serious condition of exhaustion from vomiting, pain, and distention. She had retained no food for a number of days, and was very thirsty. Her stomach was twice washed out, and a pint of warm milk injected, which was retained but a few hours. A little gas and considerable blood passed the bowel. The abdomen was tympanitic and the colon distended.

Examination per rectum revealed an empty lower rectum, but at the extreme point reached by my finger, which is rather a long one, a cancerous growth could be detected as large at its lower end as an egg. This could also be felt above the pubis by palpation.

February 15th.—Left inguinal colotomy was done, and immediately relief afforded to the distended colon.

March 13th.—The patient had made a very excellent recovery, since nourishment had been well retained, and evacuations had been thorough through the colotomy. To-day, with the assistance of Drs. Murray and Curtis, I removed the lower portion of the sacrum, through an eight-inch vertical incision in the median line, from the base of the sacrum nearly to the anal margin. The portion of the rectum uncovered was quite sound, but was dissected out so as to drag it down, and with it the cancerous mass, which was six inches from the anus. At that part the attachment to the pelvis was firm, and it was only after entering two fingers into the peritoneal cavity anterior to the rectum to handle it the better, and after ligaturing and cutting free the meso rectum, that the mass was brought down into the wound. This being done, it was found easy enough to drag down more of the rectum. This was done, and sound gut above the disease was readily brought down to meet the sound bowel above the anus, where it was cut off, because the intermediate rectum was much bruised in the handling. The peritoneal cavity was closed by a few sutures, uniting it to the anterior rectal wall, and the cut edges of the bowel united by a double row of sutures of fine catgut. There was no tension on these edges, owing to the free drawing down of the sigmoid flexure, and it was evident I could have resected more of the latter if it had been needed. The gut was completely closed and laid back in the pelvis. A light packing of iodoform gauze was laid upon it, and the superficial wound closed. The operation throughout had been comparatively free from hemorrhage.

On the second day fecal matter was evacuated per anum. On the third day the posterior wound was opened on account of a little foul pus, and a small opening was found to have taken place between the posterior sutures of the gut. When she left the hospital some weeks after, in good condition, there was still a small fistula in the centre of the sacral cicatrix, but an adhesive strap controlled the discharge. The rectal movements were perfect. During the summer she became robust and well, attending to her household duties, and having comfortable daily evacuation. The sacral fistula healed entirely.

In November, however, the old symptoms recurred, and when I saw her, nine months after the Kraske resection, there was a recurrence of the malignant growth in the pelvis about the cicatrix. This underwent a rather rapid development, though the patient looked well and continued about her home duties. The obstruction now became troublesome, and the sacral cicatrix showed cancer infiltration, and discharged fæces through a reopening of the fistula.

The left inguinal colotomy has required reopening, and she will undoubtedly have her life prolonged somewhat thereby, from arresting the fecal irritation of the rectum.

Case V. *Strangulated Hernia — Gangrenous Gut incision—Longitudinal Suture—Recovery.* — On May 13, 1891, I was called by Dr. Strong, of Long Island City, to see Mrs. K. C——, an elderly lady of fifty-five years, who had had pain and vomiting from an incarcerated right inguinal hernia for ten days. During the three latter days she had had grave changes in symptoms, with vomiting almost constantly, and for one day of a most offensive yellow fluid fecal matter. She had fallen into the usual shocked and apathetic state, with foul tongue and breath, thirst, weak pulse, 126, and inability to retain anything. The abdomen was distended, no movement had taken place for ten days. I operated at once under ether. The hernial sac was the size of a hen's egg, thickened, filled with fluid and a knuckle of very dark adherent gut. On being released and drawn down, a circle of gangrene less than a half-inch in diameter was seen where the ring had pressed upon it. It was so far sloughed as to be just ready to fall out. It was evident that either resection or artificial anus, or some form of suturing would be needed to repair it. I chose the suture. If I had sutured the bowel surface on opposite sides of this slough one way, it would have narrowed the lumen to such a degree as to cause stricture. If in the opposite way, it would have made an elbow that would have made obstruction. I therefore made a longitudinal cut of the bowel-wall, two inches long, with the slough as its centre, and sutured the edges of the cut in such a way as to make an elbowed bend of the gut with the cut splitting up the flexure crease. Two rows of silk sutures were placed round this cut and the parts washed and dropped back. The sac of the hernia was dissected out and the ring closed. Primary union occurred and an uninterrupted convalescence ensued. A large fluid fecal movement took place a few hours after the operation. The patient has never had a bad symptom and is now in good health, the functional action of the bowel being perfect.

Case VI. *Cancer of the Stomach—Gastro-enterostomy.* —Mr. G——, aged sixty-three. For two years has had symptoms of gastric trouble. During the first year had dyspepsia, frequent vomiting, but no pain or tumor. During the past eight months has had more vomiting, moderate pain, and a perceptible tumor, which he unwisely concealed. Two weeks before I saw him he again consulted his physician, Dr. Shufelt, of this city, having emaciated rapidly, though having strength to be about his house and conduct his business. His vomiting now consisted in large accumulations of what he had eaten and drunk for a day previously, none of which seemed to have left the stomach. The bowels were quite empty. Occasional gnawing and crampy pains occurred at the pit of the stomach, and a tumor was found in the epigastrium.

I saw him December 4th. Dr. Shufelt's diagnosis was confirmed. The man's cachexia, emaciation, continued emesis, and the tumor were in evidence. The latter was unusually low down, being a hard flat mass the size of one's fist, with its centre at the right of the navel. The stomach-tube brought away a quart of sour, undigested food and milk, and the organ was washed out with an alkaline liquid.

The patient's pulse was thready, and condition wholly unpromising. Yet his energy and will were so strong that I decided, after endeavoring for three days of preparation by stimulants, nutritive enemata, and stomach washing once daily, followed by introduction of warm, soft nutriment into the stomach, to fit him for exploration and possible gastro-enterostomy.

December 7th, at his urgent request I operated, under ether, assisted by Drs. Shufelt, Fisk, and Dunham. The stomach was found greatly dilated and pouched in the left hypochondrium. The pylorus and anterior wall for a space of four or five inches was a solid, flat, malignant mass, distorted and dragged below the level of the navel. Extensive cancer infiltration stretched into the mesentery. Displacing the transverse colon and omentum, I seized the nearest coil of small intestine below and behind the stomach, and drawing it into the wound applied Senn's method of determining the location of the duodenum. Holding the loop first seized, I drew out a foot and a half of the bowel and found it appreciably thinner in the texture of its walls, showing that it led toward the distal part. Replacing it, I then drew in the opposite direction and found, in less than a foot, that it could be dragged no farther and that its walls were perceptibly thicker. For further corroboration I slipped my fingers down the face of the gut into the abdomen, and found it secure in the duodenal region. I now quickly dragged up the most convenient sound portion of the anterior wall of the stomach, and applied two parallel rows of continuous fine silk suture to unite the wall of the bowel and stomach for full three inches. Having previously secured the abdomen against the entrance of fluid by packing with flat sponges, around and within the lips of the wound, but not putting them wholly into the cavity, I opened the bowel and stomach by free incision two and a half inches long, and half an inch from the line of sutures, and secured the apposition as detailed elsewhere.

Repeated flushing of the exposed parts with hot water maintained cleanliness. The united portions being dried, were dropped back and the abdomen closed. The entire anastomosis occupied but twenty minutes. Fine black silk and straight needles alone were used.

The latter part of the operation was done with the patient's head lowered to maintain heart action. After operation he rallied well for two hours, but then failed, and, in spite of saline infusion of more than a pint into a vein at his elbow, as well as stimulating enemata and hypodermics, he failed and died.

Case VII. *Lateral Anastomosis by Catgut Rings for Chronic Obstruction—Death.*—December, 1889, Charlotte B——, aged forty-four, was transferred to my care in an exhausted state from symptoms of chronic intestinal obstruction, with continuous vomiting of yellow and offensive fluid, persistent cramps, and intense thirst, and emaciation which had been progressive for two months, but which had existed in moderate degree for the previous year. A large tumor of the abdomen was observed, containing fluid and gas. December 22d, I did laparotomy, discovered a small malignant stenosis of the ileum, with enormous dilatation above it resembling a stomach. The conditions seeming favorable, I did an immediate lateral anastomosis, uniting the intestine above and below the stenosis by aid of catgut rings. The patient's condition was not warranting resection of the malignant portion. The time of anastomosis was twenty minutes. The patient survived six hours, dying from the exhaustion incident to her grave condition.

Observations.—It has been with uninterrupted interest that the surgical world has for several years watched the reported researches in the field of intestinal surgery for the development of additional resources to enable it to cope with the complex accidents in this field. Experimental work has shown that the use of artificial aids in restoring the intestinal canal by anastomosis is feasible by such means as bone plates, catgut rings, segmented rubber rings, or vegetable plates. Their use has largely been confined to experiments upon dogs, and their boasted advantage has been that there will be a reduction of time at operations. While not denying the utility of experiments upon dogs (for I am myself indebted largely to this work for valuable lessons), I would emphasize the contrast that exists between operative work in dogs and in the human subject, on account of the relative quality and reparative action in the two species. It is extremely easy to accomplish satisfactory recoveries in surgery of dogs' intestines by almost any method.

Accumulating evidence of the methods applied to the human body may now be weighed by those of experience in this field. From evidence of published and unpublished cases, it can be shown that in the hands of even competent men, using any of the artificial aids to accelerate the operation, the accidents may occur of having leakage, or suppuration, or hemorrhage, or obstruction from plates, or irritation of the canal from so considerable a foreign body. The question of time gained during what is usually a prolonged operation, perhaps at most five or ten minutes, in the face of the uncertain advantage of bone plates, etc., is one that in my opinion is greatly outweighed by the superior advantage of having absolute security against leakage, blocking, etc., by the method of simple suturing.

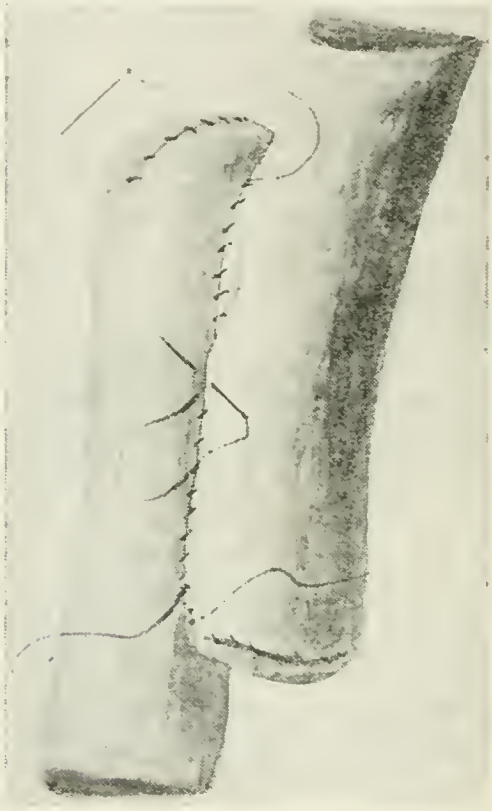

Fig. 1.—Suturing Intestines in Apposition before Incision.

The technique of the latter procedure is a matter of easier accomplishment and far greater satisfaction in its results than that of the newer methods. The fifteen recently reported cases of gastro-enterostomy by Senn, seem to me to give results inferior to the older method by suturing.

There is one feature of the operation of anastomosis which has heretofore received no special attention, but which I believe to be of the very greatest moment in determining the lasting benefit of the operation, that is, the question of stenosis of the newly made orifice. The law of cicatricial contraction, that operates so effectually in closing accidentally made fistulæ into the intestinal tract, or comparatively large ulcerations between the gall bladder and the intestines, is here the direct antagonist of the surgeon in his endeavor to create a permanent and adequate anastomotic opening. The incised opening made for the use of Senn's plates is about one inch and a half in length, and the contraction of such an opening sometimes with great rapidity, has in some cases rendered it entirely inadequate to its service. Not many autopsies remote from the date of operation are as yet recorded. Three of my cases of lateral anastomosis illustrate the subject admirably. In the first, done in

1888, between the ascending and transverse colon, where I had used Senn's plates, the patient dying six months after operation, the aperture, which was one inch and a half in length, had contracted to three-fourths of an inch, and was sufficient for its purpose only when laxative medicine was constantly given. In the second case, the patient dying six months after anastomosis, with catgut rings, the opening had contracted from one inch and a half down to a half-inch. In the third case, eight months after lateral anastomosis of the sigmoid by suturing, the

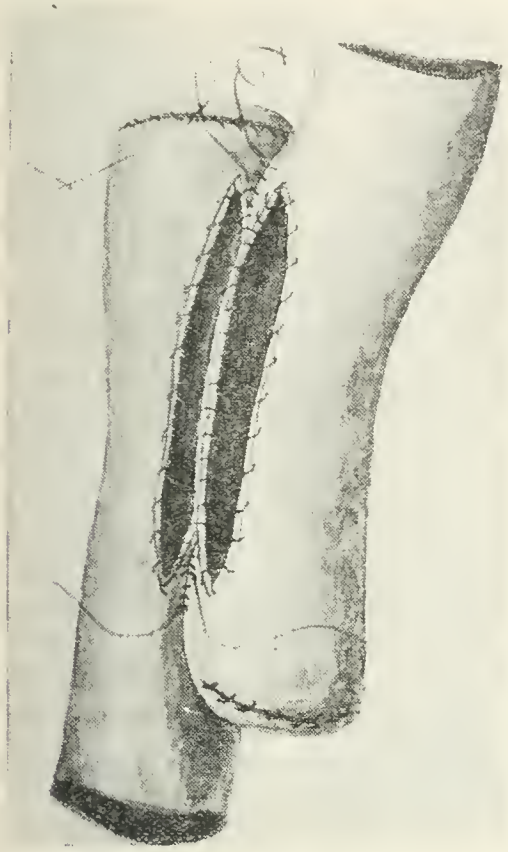

FIG. 2.—After Four-inch Incision and Sewing the Edges.

aperture contracted from three inches to one and a half. This was perfectly competent to do the functional work of the bowel.

These results were relatively good, but not so perfect as that which so far has been brilliantly demonstrated in two of the other cases just reported, where lateral anastomosis by suturing around a four-inch opening was done with instant and absolute functional restoration.

I believe the future utility of lateral anastomosis lies in making openings four inches in length in the sides of adjacent bowel. This, I contend, is almost impossible with bone plates, and only to be done by very long catgut rings or vegetable plates, with less security and as much consumption of time as by suturing. The contrast is enormous between dropping back into the abdominal cavity a beautifully sutured, absolutely tight and flexible anastomosed end of intestine to any position in the abdomen which its natural surroundings demand, and the returning a huge bunch of bowel, inside which there is a pair of five-inch plates of bone or raw potato, to remain as irritating foreign bodies stimulating peristalsis, and tugging at the wound until they are softened enough to be swept on by the current, or, as in one of Senn's cases, to be vomited up after dangerous retching.

As regards time, even were it proved that a hand equally expert at each method could do that by plates a few minutes quicker, the relative advantage of the two procedures for safety still lies with suturing.

But, as a matter of fact, I have found that to do thoroughly a lateral operation in the living subject, by either plates or rings, takes twenty or twenty five minutes, the same operation by simple suturing, done with greatest nicety and perfect security, has taken not more than minutes.

The six cases of lateral anastomosis of bowel to bowel as well as the gastro-enterostomy and other intestinal sutur ings, which I have reported (*Philadelphia Medical News*, June 1, 1889), speak strongly in favor of the uniform use of suturing alone. The one fatal one of the six lateral cases was where I made immediate apposition of an enormously distended bowel above an obstruction to a collapsed portion below it, the patient being already in a deplorably bad condition.

Since that and other experiences with great fecal accumulations, I have strongly advocated the uniform practice of first creating an artificial anus, allowing a few days for recuperation, and avoiding the fecal toxæmia, which I believe is a serious factor when the stagnant flood of fluid fæces flows freely into the unused and receptive bowel eager for absorption.

The perfect technique of suturing will be found in the following method:

Bring the two surfaces that it is proposed to unite well up in the wound, and surround them by small compresses of gauze or towels or flat sponges wrung out of hot water.

Have at hand a half-dozen fine cambric needles threaded with ordinary finest black embroidery silk that has

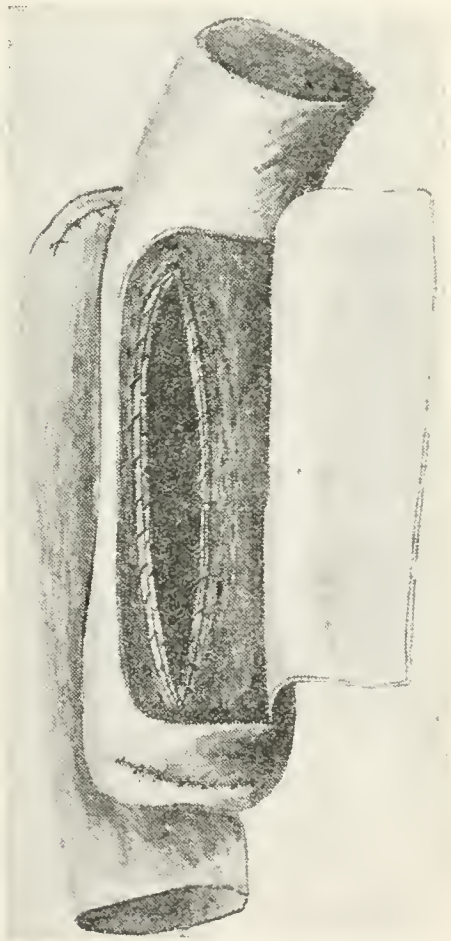

FIG. 3.—Complete Anastomosis. Window cut out to show interior.

been well boiled and kept in alcohol. Cut in lengths of not more than twenty-four inches and tie with a single knot at the eye of the needle, with one end cut to within two inches. Apply two parallel rows of continuous Lembert suture, a quarter of an inch apart, and an inch longer than the proposed cut (Fig. 1.). Leave each thread with its needle attached at the end of its row. Now open the bowel by scissors, cutting a quarter of an inch from the sutures, both rows of which are to remain on one side of the cut. Make the bowel opening four inches long. Ap-

ply clamps temporarily to several bleeding points, pinching the entire thickness of the cut edge without hesitation. Apply no ligatures. Treat the opposing bowel in the same manner. The clamps remaining *in situ*, the parts are quickly rinsed with water. Another silk suture is now started at one corner of the openings and unites by a quick overhand the two cut edges lying next the first rows of sutures (Fig. 2). The needle pierces both mucous and serous coats, and thus secures the bleeding vessels, from which the clamps are removed as the needle reaches them. This suturing is then continued round each free edge in turn, and all bleeding points are thus secured more quickly than by ligature. The serous surfaces around these button-holes are then rapidly secured by a continuation of the sutures first applied, the same threads being used, the one nearest the cut edge first. The united parts are again rinsed with water and dropped into the abdomen.

In conclusion I would reiterate my conviction: 1. That the attempt to simplify the technique of lateral anastomosis by bone plates and other devices has not improved it. 2. That lateral anastomosis properly done is eminently the safest and best method of restoring the canal in most cases. 3. That simple and thorough suturing with a fine silk continuous suture, applied after the manner detailed, is most satisfactory. 4. That in order to allow for the inevitable tendency to stenosis an aperture four inches long should be made between bowels. 5. That scarifying opposing surfaces is entirely unnecessary to quick and solid repair.

A CONTRIBUTION TO THE STUDY OF HEADACHES, WITH PARTICULAR REFERENCE TO THEIR ETIOLOGY AND TREATMENT.[1]

By JOSEPH COLLINS, M.D.,

NEW YORK.

By the term headache we understand a painful condition referred to the head, associated with more or less mental incapacity and intolerance of light and sound, generally in proportion to the cause and intensity of the suffering.

In proportion to the amount of suffering inflicted on humanity by headache, it has been less studied and more treated than any disease in the category. No age, no period of life, no condition of bodily excellence is entirely exempt from it. Like all other diseases which are so extensive in their dissemination, and so little understood as regards their pathology, their treatment has involved most of the drugs in the Pharmacopœia and many additional measures.

It has been estimated that fifteen per cent. of all patients suffering from nervous troubles claim headache as their principal symptom. Three periods of life seem especially prone to it, viz.: 1st, from second dentition to puberty; 2d, about the time of the menopause in the female; and 3d, between twenty and twenty-five, and least of all, in old age. Considering the predisposition of the female to the occurrence of pains at the catamenia and menopause, and taking into consideration the exigencies of her life and surroundings, it is not surprising to find that headaches occur three and a half times as often as in the male. Headaches occur more during the winter season than during the summer. They are more apt to occur in those who lead a sedentary, studious, indoor life, and particularly in those who habitually overwork mentally at some one particular thing without variety. A hereditary tendency and a repetition of the attack is a large predisposing factor, particularly in female patients, and not only a direct transmission is inherited, but a proneness to pain due to a neuropathic temperament. All writers agree on this subject, in saying that headaches occur three or four times more frequently in patients of neurotic temperament than in those of a sanguine or phlegmatic. They are without question the most common concomitants of systemic disturbance and disease, and in many so-called functional nervous diseases a headache is a prominent symptom, as, for instance, in chorea, where Hughlings-Jackson and Herman estimated that seventy per cent. of all children with chorea suffer from headache.

It occurs most often in those whose manner of living prone them to disability, whether it be from the indulgences in those excesses that result in cell depravity, as in the higher classes, or from the disobedience of hygienic and nutritive laws which are followed by a proneness to all diseased conditions in the impoverished. And lastly, as regards general conditions, it is apt to occur repeatedly in the same subject. One attack tends to another; nerve-centres when once disturbed in a particular direction are more easily so upset again than in another way. A sort of a headache habit, as it were.

All manifestations of head pains may be classified under one of the three following conditions:

1. They may result from a disturbance of the kinetic energy stored up in the sensory areas of the brain, and manifested by an explosion or storm which expends itself principally in the ophthalmic division of the fifth nerve, and is known as migraine.

2. They may result from the altered condition of a nerve or nerve-fibrillæ, brought about by some irritant; neuralgia.

3. They may result from any condition not giving rise to either of the above. And it is with this last variety alone that this paper is concerned. Headaches may be classified as to their etiology, their pathology, their location, their symptoms; but according to their etiology is most satisfactory for therapeutic purposes. The most recent, and probably the best classification, is that of Dana's,[1] apparently a modification and improvement of the one given by Erb. That classification is as follows:

I. Hæmic Causes.—(*a*) Anæmic. (*b*) Diathetic states (gout, rheumatism, diabetes, etc.). (*c*) Infections. (*d*) Uræmia.

II. Toxic Causes.—Lead, alcohol, tobacco, drugs, etc.

III. Neuropathic States.—Epilepsy, neurasthenia, chorea, hysteria, etc.

IV. Reflex Causes.—Ocular, dental, naso-pharyngeal, auditory, dyspeptic, sexual, uterine, etc.

To this should be added, I think, under the heading of hæmic causes, at least hyperæmia, and under the diathetic states at least the lithæmic, and perhaps auto toxæmic conditions which, although perhaps part and parcel of the others, are of sufficient importance to merit the dignity of a separate heading. Then a transference of diabetes from under the diathetic condition, and placing it side by side with uræmia.

Anæmic headaches arise from two entirely different conditions: one in which there is an impoverishment in the nutritive powers of the blood, and second, where the vascular tension is diminished, a condition which may be, but not necessarily so, associated with oligocythæmia. As a result of the first condition, the cells of the sensory areas in the cortex have their normal stability interfered with, so, although they may not in themselves be the seat of pain, they allow the pain to become manifest. This is the variety of pain most common in young women after puberty, and is associated with that symptom complex of the general anæmic condition which is familiar to every physician. And particularly apt to occur with this condition are pains in other parts of the body, neuralgic like in character. The headaches associated with diminished blood-pressure must be explained in a somewhat similar manner to those of anæmia, excepting that in these conditions the sensory areas do not suffer so much from lack of proper nutrition as they do from proper stimulation to functionate normally, and so fall into sluggish and perverted ways. Likewise must we explain the headaches arising from a condition of the blood in which there is an excessive number of corpuscles proportionate to the liquid element. And here it may be said that the administration of many substances or factors causing a rise of blood

[1] Read before the New York County Medical Society, February, 1892.

[1] Medical News, Philadelphia, 1889.

pressure, which is not long continuous and followed by depression, is apt to be followed by headache as an after-symptom; and in this way are to be explained the headaches resulting after indulgence in diffusible stimulants, a condition which occurs so exquisitely after a champagne excess. Fevers and excitement, and mental irritants in general, cause headache in a precisely similar manner.

Of the hæmic causes the most interesting, however, come under the subdivision of diathetic conditions, for here we can trace with almost scientific accuracy the relation between cause and effect; and particularly is this so in the subdivision of the diathetic state, of which we shall have most to say, namely, lithæmia; a condition which was defined in 1874 by Murchison, in his Croonian Lectures, as an indication of a morbid state of the blood, due, in his opinion, to the abnormal disintegration of albuminous matter in the liver, bringing about an excessive production of uric acid and an excess of lithates in the urine, or lithuria. This term is still most largely used to express the now familiar symptom complex, but the preferable one of uric acidæmia, suggested by Von Jaksch, will probably supersede it.

To the labors of Dr. A. Haig, of London, we owe a large part of our recent knowledge concerning the manner of the production of uric acid, and the ways by which it produces symptoms. Haig claims that the symptoms are due, not to excessive production of uric acid or its compounds, but to the retention of it in the system, whether it be in excess or not; and he shows that when the urine excreted during a lithæmic headache is carefully separated from that excreted before the headache began, or after it has left off, an excess of uric acid relative to the urea is always found. Before the headache begins the relation will probably be 1 to 40; after it will be 1 to 20; the normal relation being about 1 to 33. In speaking of his own case personally, he says: "I soon found out that in influencing the excretion of uric acid I could influence the headache also; that acids which diminished the excretion of uric acid in the urine relieved or removed headache; while, on the other hand, alkalies increased the excretion of uric acid and made the headache worse. Therefore any condition which causes an excess in the production of uric acid, providing there is also an abnormal retention of it in the blood, will give rise to headache. This state of affairs may be brought about by the taking of an excessive amount of nitrogenous food, the normal metabolism of which has for one of its by-products uric acid; or it may result from a deficiency of the factors concerned in oxidizing these albuminous substances, and this inability may be inherited or acquired. In this way is to be explained in a vast degree the headaches occurring in people of sedentary habits, indoor occupation, and in those taking very little or no exercise; and to this also, as a contributing factor associated with diminished blood-pressure, arising partly from over-heated apartments and indulgence in enervating habits, must we attribute the extraordinary prevalence of headache in the American woman as contrasted with her sister, the Briton, always bearing in mind the temperament and frequently inherited neuropathic condition in the former, so as to render the tolerance of pain less easy. The introduction of food stuffs other than nitrogenous must not be neglected in their relationship to the production of uric acid, and of these the most important are substances rich in the potassium salts."

We are familiar with the patient who has inherited a weak liver, or who has a bilious headache, and who knows that periodically, and particularly after some unjustifiable digestive feat, he will suffer from an indescribable malaise, lack of cerebral activity, and stupid, heavy frontal ache, rarely occipital. Formerly we were content to give him a blue pill, "to stir up his liver," without asking the cause, but now we trace the relationship between his inability to take the substance of which uric acid is an effete product and his organism, particularly the liver, for it is here that most of the oxidation goes on—to complete the metabolism. It matters not whether he has received this inability as a parental legacy, or whether it has been developed. As a proof of the fact that the headache is to be attributed to the uric acidæmia, it may be stated that it has been proven experimentally that the period of depression and headache is often preceded by a period of mental exaltation and well being which is concomitant with a rise in blood-pressure, and a relative diminution of the uric acid in the urine preparatory to its retention in the blood.

In the winter number of *Brain*, Dr. Haig says that he found that, by retaining or storing up uric acid for a day or two by means of acid, he could accumulate it in the body, and by then giving an alkali he could bring out a lot of it into the blood and the urine and produce headache at will, and show at the same time that the headache is proportional to the excess of uric acid over the urea, and not to the amount of alkali used to bring it out.

While in this connection, it is interesting to note that the peculiarly aggravated and persistent depression after the grippe—the discussion of which has lately been occupying the attention of this Society—which often becomes suicidal in form, so intense is it, has been shown to be dependent largely, if not entirely, on the retention of uric acid in the blood. During the febrile period, or period of sthenic activity, the urea is increased and the uric acid is stored away, which is brought out in the system during the period of sluggish metabolism, at the time of and after convalescence.

Although the previously described condition may probably come under the termination of self-intoxication, the term auto-toxæmia is generally limited to a narrower conception, and that is the absorption, from the alimentary canal principally, of certain alkaloidal substances generally termed leucomaïnes, which are products of albuminous decomposition brought about either by the activity of cells, before or after entering the body, or by processes of digestion, as by unorganized ferments. The headache due to the absorption of extractives is to be distinguished from that due to leucomaïnes in many particulars, and the conclusions to be drawn as regards treatment are quite removed.

As regards the headache of diabetes, it is to be remarked that long ago De Chaumont pointed out that when glucose is in excess, some inhibitory influence seems to be exercised over the elimination of the extractives, so that they appear less in quantity, but to all intents and purposes the headache is the same clinically. This is proven by many authorities. In a discussion of Dr. L. C. Gray's paper on the "Manifestations of Uric Acid on the Nervous System," one of the gentlemen in discussing the subject of headache said, that in his own person the headache of diabetes, from which he previously suffered, was apparently the same as that from uric acidæmia from which he then suffered. Whether in diabetes the actual formation of the extractives is prevented, or merely their activity, cannot as yet be positively affirmed.

Regarding the headaches of fevers and infections, they are in all probability due to either the absorption of extractives or leucomaïnes, or both, and associated with a condition of disordered blood-pressure. In malaria this has been unquestionably proven.

Under the toxic causes of headache we have those substances, the most of which are used remedially, as quinine, alcohol, iron, lead, tobacco, opium, etc. As to how some of these cause it, we have previously discussed; particularly those which have marked action on blood-pressure, and as for lead and iron, although it is a familiar fact that they produce headache, it is now a matter of but little speculation to say they cause this condition by bringing about a retention of uric acid and laying it up as a reserve fund for the production of uric acidæmia, which is manifested by a headache that corresponds clinically with the headache of uric acid poisoning, and is most readily relieved by the same measures.

Of the neuropathic headaches but little can be said

concerning their etiology which is new or of importance, so long as our pathological knowledge remains in as obscure a condition as it is at present. In these neuropathic states the headaches of hysteria and neurasthenia are the most difficult of explanation, and particularly the latter; and our only assistance is to revert to the disorders in circulation and the resulting perversion in the functions and secretions of the body which in themselves cause the production of a morbid material, or allow of its introduction into the economy so as to act on certain areas and cause pain; and associated with this there is a psychical and bodily condition which permits the patients to suffer exquisitely, particularly in repetitions of the attack. In hysteria the pain is probably the result of molecular or nutritive changes in the centre for sensation in the brain. In other nervous diseases where headache is a prominent symptom, as in chorea particularly, and somewhat so in epilepsy, we have already found corporeal changes or hæmic dyscrasia which are sufficient to account for this symptom.

In the reflex causes we have a large and constantly increasing field for consideration. It has been attempted time and again to explain all forms of functional cephalalgia along this line, and the arguments of many of its advocates, particularly the eye specialists, are often so potent as to be, seemingly, sometimes invulnerable.

In reviewing the literature of this subject in something over a hundred articles, I find that they are responsible for much more than their share of these writings, and that frequently their statements, as regards the importance of their espoused specialty in producing headaches, are simply appalling. That a comparatively large number of headaches have their origin in defective or diseased ocular apparatus, no one will deny. And particularly is this so of the headaches of children, where, if they are not traceable to inherited conditions, are in most cases dependent on the eye. The defects here most often are unquestionably hypermetropia and astigmatism, and of the former it may be said that when it causes this symptom, probably a high degree of refractive trouble will be found; in the latter, more often a very slight degree. Of the other ocular troubles trachoma will be found to be responsible for a few headaches, as will also simple chronic ophthalmia. Of the remaining reflex causes, those from the naso-pharynx and teeth are undoubtedly most important. They probably both act largely through the vaso motor nerves, causing a vascular spasm which in return causes the pain of headache. This is particularly so of the headache resulting from decayed teeth, the immediate effect being brought about by disturbances in the superior cervical ganglion.

Of the naso pharynx and auditory, there are but few affections of these organs but what may give rise at one time or another to headache; but they are not so frequently observed as are the uterine, where it is frequently the result of ovarian irritation and inflammation, and corporeal and cervical disease, and almost always associated with some disturbances of the alimentary tract, as the paroxysm is apt to be worse in the afternoon and evening, and particularly so where there is any abdominal gaseous distention.

The dyspeptic, bilious, and headaches from constipation are probably more largely dependent on the absorption of toxic matters into the system than from a purely reflex cause. These headaches do not differ widely from those already described under the auto-toxæmic variety, excepting in so far as they are associated with symptoms referable to the alimentary canal directly. Their clinical manifestations very closely correspond.

The headaches referable wholly to the sexual organs are the rarest of all the reflex varieties. A peculiar case, which was observed some two or three years ago, was that of a boy who suffered from a severe spasmodic cough and headaches, for which the only discoverable cause was a partly imperforate urinary meatus, which, on being operated on, was followed by a relief of the reflex troubles.

Of the headaches dependent on constitutional diseases we shall have nothing to say. They are caused by the direct action of the morbid material on the pain areas, or reflex in nature. They arise from the various forms of traumatism to the head, or they are the result of some intra-cranial disease.

In attempting to discuss the treatment of this distressing symptom, one is at once awed and appalled by the number of things which are referred to for their curative effects by the various authors on this subject. The specifics vary as widely here as they do for phthisis. One writer alone gives sixty-nine different substances used for the relief of headache. We shall content ourselves with the mention of a few which have been found from personal experience, and gleaned from the experience of others, to be at least not specifics but certainties. And of these there are two which stand out prominently above all others as pure medicinal measures. They are the salicylates and the chloride of ammonium. Of the former, we will find that choosing either phenol salicylas, ordinarily known as salol, or salicylic acid itself, will be productive of most good. This class of substances are without question of most importance in the diathetic, the toxic, and auto-toxæmic states—the salicylic acid uniting with the uric, forming what may be termed saliuric acid, which is innocuous and easily removed from the system. The salicylates are also powerful anti fermentatives.

This, combined with the administration of a mineral acid to prevent the formation of uric acid compounds and to dissolve urine out after it may have once formed, will be found most valuable. Ammonium chloride has been employed both externally in a saturated solution, and internally in large doses, for the relief of headache, and it is deservedly one of the most popular remedies. It probably owes the larger part of its efficacy to its action on the liver and mucous membrane of the stomach, and is particularly valuable when the headache is associated with loss of appetite, sickness, bad taste in the mouth, fulness in the stomach, flatulence, coated tongue, and stuffiness of the bronchial tubes. Wafers containing from ℥ss. to ℥j. should be administered every two to four hours for three doses.

Headaches dependent on diminished blood-pressure are frequently relieved by the simple act of sipping, as, for instance, taking a glass of cold water by mouthfuls. It has been shown experimentally, and practically demonstrated, that during the act of sipping the blood-pressure rises, which is followed by a slight fall after the cessation of sipping, to be followed, however, by a secondary and permanent rise. Krönecker attributed this rise after sipping cold water to the partial abolition of the inhibitory action of the vagus on the heart. An increase of blood-pressure may be brought about also by mastication, sniffing irritant substances, exposure to cold and excitement; and by means of this last agent must we account for the disappearance of functional headache when the attention is engaged. Of course those headaches may also be relieved frequently by the administration of the cardiac neurotics which cause a rise in blood-pressure, but unless their use is continued the action is evanescent; and particularly is this so of the diffusible stimulants which many patients, particularly females, find relieve them, but frequently at a disastrous expense, that of forming the habit.

In congestive headache we undoubtedly get best results from the use of ergot internally and derivatives to the extremities, or external use of cold frequently assisted by a dose of bromide as a vaso-motor equalizer. And in this condition galvanism to the cervical sympathetic will frequently be followed by relief.

When the headache depends on simple stomachic hyperacidity without constipation, the pain being located principally at the junction of the hairy scalp and forehead, the administration of bicarbonate of soda will give relief; and, on the other hand, the pain of headache when situated just over and between the orbital arches, and de-

pendent on sluggish stomachic digestion attended by constipation, is most expeditiously treated by giving acids and simple bitters. It need not be said here, as it has so often been said with emphasis, that in reflex headaches the causative factor having been overcome, the headache will disappear. Then we need not speak of the astigmatism or hypermetropia, which must be properly corrected, or the esophoria or the exophoria which may demand an operation before the consequent pain will disappear. In the same way may be dismissed the auditory, the nasopharyngeal, and those dependent on decayed teeth, etc.

Words of warning concerning the use of recently introduced nervines—products of coal-tar distillation—cannot be sounded too loudly, particularly in reference to antipyrin, phenacetin, antikamine, coaline, and other proprietary substances; not but what they frequently relieve a transitory neuralgic headache, but they in no way exert an influence to cure the root of the evil on which the origin of the headache is based, and by their repeated use they create a necessity for their continuance which becomes sooner or later nothing more than a habit; for I am sure I have two ladies under my care at present who are almost held in obeisance to antipyrin by their having abused its use.

It is unnecessary to speak in this connection of the treatment which should be employed during the interval; it can be summed up in one word, by saying that it should consist of preventing or overcoming every perverted condition on which the pain may depend, and placing the system in such a condition that it will be better able to combat the pain and make light of it when it does come.

The mention of all those substances which act by improving the general nutrition would be but a tedious and useless task. They vary as do the many causes of headache. One measure, however, which is more universal in its application than any other is water, and principally its external use; although the benefit accruing from its internal use is not to be slighted, acting as it does in elevating blood pressure, in flushing the kidneys, and so facilitating the removal of poisonous eliminatives, and by its direct action on the walls of the intestine• stimulating peristaltic action and assisting in collecting the fecal matter and diminishing its consistency, so that it may be readily gotten rid of; also the influence which it exerts generally on those glands whose functions are mainly excrementitious and purifying. It is, however, from the external use of water at varying degrees of temperature that we are to expect the most beneficent results, by restoring the tone to the entire organism and principally to and through the nervous system. The therapeutics of water is a large field by itself, and requires extensive space for its discussion; but it may not be amiss to state that, as a general rule, those headaches dependent on hæmic and vascular changes will be most benefited by the application of cold water in such a way as to get an irritant effect, followed by a moderate but thorough reaction. Such may be obtained by the shower, plunge, or needle bath, and by the Scottish or French douche or the graduated spray. These measures, applied regularly and briefly, will in many cases be followed by the disappearance of the atonic condition of which the headache is but a manifestation. The application of cold water abruptly not only in itself stimulates the peripheral sensory nerves, but the mechanical irritation of the contact of the water does likewise. A stimulated molecular transformation throughout the entire body, with a concomitant excitation of function, is the result. The contraction of the smaller blood-vessels raises blood-pressure, and this continues for some time following the application of the water, and important centres thus obtain their proper stimulus.

Headaches dependent on neuropathic conditions, on the other hand, will be most benefited by applying water in such a way as to combine its sedative and tonic action, and this is most readily done by means of the cold sheet packing, or perhaps a modification of the wet packing which will not result in storing up too much of the heat which should radiate from the body, but which will exercise an action on the sensory nerves which, although not greatly stimulating, will be followed by a very slight contraction of the capillary blood vessels, and the transmission of a sedative influence to the cortical areas which, if not sensory entirely, are something analogous to it—the "peace of mind areas," perhaps. In this way many of the neurasthenics and those patients who have headaches from fretting and fussing will find relief.

And before closing, one word concerning the pathology. Statements concerning the exact location of the seat of pain rise only to the dignity of a conjecture. Dana says, rather dogmatically, headache is, strictly speaking, a form of neuralgia, and its seat is in the external envelope of the skull and dura mater. Another writer locates it in the sympathetic or fifth pair of nerves alone; while others, again, call it a neuralgia of the cortical substance. There are clinical phenomena in the course of some headaches to give ground for each of these theories. However, judging from experimental facts, as where Ferrier proves that destruction of the hippocampus convolution gives analgesia on the opposite half of the body; and from analogy, considering the discovery of other areas which have been recently specialized, as for heat, for instance, we might be tempted to grasp at a cortical pain area. All pain as a form of consciousness must be perceived by nerve-centres, and as pain does not partake at all as an important factor in low organisms, it is rational to conclude that higher nerve-areas preside over it. And although there are without question pain-areas in the inter and basal ganglia, we are tempted to conclude that, judging from the other functions of those parts, that they are in correlation and sympathy with higher areas. And if such a pain-area could be proven, our task of explaining a good many headaches would not be so intricate as it is at present; nor need it necessarily conflict with many of the other theories, of vaso-motor spasm, disturbance in the trigeminus, etc., for these might still be the ways and means by which the areas recognized or manifested the pain.

153 Lexington Avenue.

Leprosy in Japan.—Another missionary who devoted himself to the succor of lepers has just completed his sacrifice by giving his life in their service. Father Testevuide, who may be called the Damien of Japan, established the first leper house in that country in 1886. At that time no provision whatever was made either by the Government or the public for the care of lepers, and it was only by the most persevering efforts that the energetic priest was able to collect sufficient funds to build a leper house on Mount Fusi. This institution he personally managed till his death. His example has been fruitful, and now there are three asylums for the victims of leprosy in Japan, all apparently owing their existence to private charity.—*British Medical Journal.*

A New Anti-rheumatic.—Salophene is a derivative. It is obtained by treating para nitrophenol with salicylic acid, reducing the nitrophenol by means of zinc and hydrochloric acid into an amide, and acting upon this with acetic acid. Salophene contains about fifty per cent. of salicylic acid, and exists in the form of thin scales, tasteless, inodorous, and with a neutral reaction. It is almost insoluble in cold water, and only slightly so when warmed. Upon the addition, however, of an alkali it readily dissolves. It is very soluble in alcohol and ether. It burns with a smoky flame, leaving no residue. In the stomach salophene breaks up into salicylic acid and acetyl paraamido-phenol. These substances are excreted by the kidney, and can be found in the urine. Salophene, owing to the presence of amido-phenol, is less poisonous than salol. According to Guttmann, it is a valuable remedy in articular rheumatism, given in doses of from four to six grammes a day in pill or in the form of compressed tablets.

AN ORIGINAL DEVICE FOR CORRECTING DEFORMITIES OF THE NOSE RESULTING FROM TRAUMATISM; WITH A REPORT OF TWO CASES.

By WALTER B. JOHNSON, M.D.,

SURGEON TO THE EYE AND EAR INFIRMARY, PATERSON, N. J.

The instrumentation and the operation proposed, aim at a refracture and union in proper position, of traumatically displaced nasal bones. The instruments used are an elevator (see Fig. 1), a retentive apparatus (see Fig. 2),

Fig. 1.

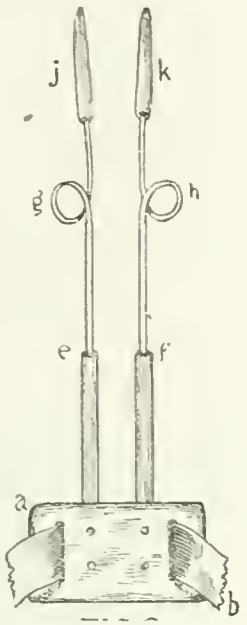

Fig. 2.

and a plaster cast to assist in retaining the parts in their proper position after the operation.

The elevator, Fig. 1, is shaped somewhat like a tuning-fork; it is so constructed that it will resist a considerable pressure; the length of the handle, *a*, *b*, should be at least six inches, to allow for the use of sufficient leverage in refracturing the bones. The prongs, *c*, *a*, which are two inches in length, round and tapering, in diameter from one-eighth of an inch at the point, *d*, to three-sixteenths of an inch at the base, *c*, should be so tempered that the interspace between the prongs of the fork may be varied from three-sixteenths to five sixteenths of an inch, according to the thickness of the nasal septum, and the indications of the case to be operated. The entire length of the instrument is about nine inches, and its tensile strength should be sufficient to withstand any possible pressure which might be exerted during an operation.

Fig. 3.

The retentive apparatus, Fig. 2, consists of a bone plate, *a*, *b*, two and one-half inches long, by one and one-half inch wide, and about one-quarter of an inch thick, having two slits through which is passed the head band for holding the apparatus in position. To this bone plate are riveted two flat wire springs, *e*, *f*, *g*, *h*; the spring coils, *g*, *h*, furnish the necessary pressure and are to be uncoiled on the application of the apparatus; at the ends of these springs two bone tips are fastened, *j*, *k*, which are of the same shape, size, and length as the prongs terminating the elevator.

The apparatus in position is shown in Fig. 3. The plaster cast, which is not shown on the cut, is to be made of several successive layers of muslin impregnated with plaster-of-Paris, and should be prepared immediately after the operation, when the parts are in their proper position, before tumefaction has occurred; it should cover the nose from the base nearly to the apex, and extend over each side, resting on the cheeks.

The operation is performed in the following manner: After adjusting the prongs of the elevator, so that the points will be as closely approximated as the thickness of the septum nasi will permit, and when the patient is thoroughly anæsthetized, pass them well up into the nostrils and under the nasal bones. The left hand is then rested on the patient's upper jaw, to be used as a fulcrum, and steady downward pressure made upon the handle of the elevator, the pressure is continued until sufficient force is developed to separate the bones and raise them into position; the force required will be very considerable, and should be made toward the most sunken side of the nose; the bones generally separate with a suddenness that is alarming, suggesting the possibility of the accidental removal of the entire nasal organ. The plaster cast should then be made, and, when the plaster has thoroughly hardened, be removed and reserved for future use. The after-treatment is not commenced until the following day. The bone tips of the retentive apparatus, after being well smeared with vaseline, are introduced into the nostrils, and the plaster cast is placed in position over the bridge of the nose and retained by strips of adhesive plaster, the whole apparatus being worn from two to four hours each morning and evening. This treatment is continued daily, the length of time during which the apparatus is worn each day depending on the degree of irritation produced thereby.

The advantages claimed for this operation and mode of treatment over the old methods are: 1. The thoroughness, rapidity, and the comparative ease with which the operation is performed. 2. The ability to maintain during the operation an even pressure on both nasal bones at the same time, or greater pressure can be exerted on either side, if required, in consequence of more extensive sinking, by simply tilting the fork. 3. The absence of any external injury, which may occur in using the forceps. 4. The fracture produced is simple, instead of compound, as in the chiselling operation. 5. The value of the retentive apparatus in preventing subsequent sinking.

This operation has been performed on the two cases which are here reported.

Case I.—G. B——, aged thirty-two, a strong, well-nourished man, born in the United States. He had a large and flat nose, the bridge of which was much sunken and deflected to the left. About five years before coming under observation he received a blow which took effect especially on the nasal bones, producing the great deformity and depression of the nose. The cartilaginous portion of the septum nasi was but slightly deflected.

January 10th.—The operation as above described was performed, and was accompanied by a moderate amount of nasal hemorrhage, the bones were uplifted and pried toward the right side, leaving the median line of the nose perfectly straight, and the bridge sufficiently elevated. The retentive apparatus and the plaster cast were used twice daily for the next ten days, the periods of time during which they were worn being increased from two to four hours for each application. At the end of this time all instrumentation was discontinued, the apparatus at no time having produced unbearable irritation. The result of the operation was satisfactory, the deformity being sufficiently corrected to entirely change the appearance of the patient's face, which presented no evidence of the previous existence of so disfiguring a nasal deformity.

Case II.—C. H——, aged twenty-seven, born in Ireland, was healthy but thin, with angular features, and a moderately prominent but very sharp, thin nose. Three

years before this time he had a fall while on shipboard, striking the right side of the nose, deflecting both nasal bones to the left. The septum nasi was also displaced to the left, its shape being concavo-convex with the convexity extending toward the right side, the tip of the nose was deflected about one half-inch from the median line. In this case it was considered necessary, before refracturing the bones, to remove a section of the cartilage; the portion of cartilage removed was elliptical in shape, the incisions were made at right angles to the plane of the septum, the direction being from behind forward and downward. At the points of the elliptical opening single incisions were carried backward and forward in such a manner as to separate the upper portion of the septum from the lower half, which was forcibly pushed toward the left side by introducing the finger into the nostril.

The operation was performed similarly to the preceding one; in consequence, however, of the extreme thinness of the nose, it was more difficult and the elevator was not so easily applied as in the first case. The position of the cartilaginous edges of the septum after the excision and refracture was good, the retentive apparatus assisted in maintaining apposition of the cut edges until the healing was perfect. The nasal hemorrhage in this case was excessive, the oozing continued for several days after the operation. The after-treatment was identical with that of the former case, the retentive apparatus was, however, worn longer to insure perfect union of the cut edges of the septum, and symmetry of the bony parts. The result of the operation was very gratifying in its cosmetic effect, as well as in the decided improvement in breathing space resulting from the replaced septum nasi, which approximated its normal position.

In case excessive hemorrhage should occur as a result of the operation, or in uncontrollable hemorrhage of the nose from any cause, the following simple and cheap method of plugging the posterior nares may be employed. No originality is claimed for this procedure, the principle involved being that of the nasal cannula of Bellocq.

The intrument consists of a Eustachian catheter of medium size, and a steel spring which will pass easily through the catheter and is about twelve or fifteen inches in length, curling upon itself at either end of the catheter as it is passed through it or withdrawn, tipped with a small, olive-shaped piece of German silver the size of the catheter with an eye drilled through it for the passage of the thread. It is used in a similar manner to Bellocq's cannula, the spring being passed through the catheter, but it possesses some special advantages, which are: 1. The catheter is smaller and more easily and painlessly introduced, and may be passed readily in children and in cases of nasal deformity preventing the passage of the larger cannula. 2. The length and pliability of the spring will permit its passage to a point easily reached by the fingers, and it may be drawn from the mouth and unthreaded. 3. The trifling cost of the instrument.

The instruments as above described are manufactured by John Reynders & Co, New York.

An Aged Couple reside at Swain Station, N. J., the man being one hundred and three years of age, and his wife ninety three.

A Home for Incurables, to be known as the House of Divine Providence, has been established at Ridgewood, N. J., by the Sisters of Charity.

A CONSIDERATION OF SOME OF THE AFFECTIONS OF TENDON SHEATHS AND BURSÆ, AND THEIR RELATIONS TO INJURIES AND DISEASES OF THE JOINTS.[1]

By ROYAL WHITMAN, M.D., M.R.C.S.,

ASSISTANT SURGEON TO OUT-PATIENTS, HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

I had intended to consider somewhat in detail primary diseases of bursæ and tendon-sheaths, but a reconsideration of the cases whose treatment had induced me to choose this subject for discussion showed that, in the great majority, affections of the tendon-sheaths were secondary to injury in which a joint was also involved, while the cases of primary disease were too few for the purpose of a paper designed to be clinical in character. I propose, therefore, to call your attention to some of the anatomical relations of tendon-sheaths, and to consider their affections with reference chiefly to their importance in the treatment of joint injuries, not limiting myself as strictly as the title of the paper would imply.

Bursæ and tendon-sheaths are practically identical in structure and function. A bursa is a closed sac upon which a tendon rests, which covers a bony prominence or lies between two tendons; a synovial sheath is a bursa which surrounds more or less completely a tendon.

The majority of bursæ and tendon sheaths are perfectly formed at birth, undergoing certain changes with the age and occupation of the individual, or developing *de novo* from the connective tissue, as occasion requires.

In structure they are composed of an outer layer of fibrous and elastic tissue, more or less adherent to the surrounding parts, and an inner layer approximating that of serous membrane, differing in the character of some of the cells, which are in places superimposed one on another, secreting mucin, which gives the contents of the sac its peculiar character.[2]

Normally there is no excess of fluid in the sac, its two layers being in contact. A tendon-sheath partially or completely surrounds the tendon, its inner layer being closely adherent to it; this sheath is not like a tube through which the tendon passes, as it is often described, but is rather like a sac folded about it, an interval remaining where the two outer layers meet, for the passage of vessels. This has been called the meso-tendon, from its analogy to the mesentery of the intestines.[3]

Not all the important tendons are provided with sheaths, however; those which have none are simply surrounded by loose connective tissue, showing that fully developed sheaths are not essential to the health or functional uses of the tendons. The statement, therefore, that the sheath stands in the same relation to the tendon as does the periosteum to bone, is an exaggerated one.

The tendon-sheaths are, with few exceptions, grouped about the wrist, hand, and ankle. I shall briefly outline their arrangement, referring those who may desire a more complete knowledge of the subject to the writings of Rosthorn,[4] Garré,[5] Schwartz,[6] Schüller.[7] and others.

At birth each finger has upon its flexor aspect a tendon-sheath reaching from the head of the metacarpal bone to about the middle of the second phalanx. In the wrist and palm there are two separate synovial sacs, each beginning at about the level of the wrist joint, the one on the radial, the other on the ulnar aspect, lying in close contact with the carpal ligaments, in the palm being more superficial and adherent to the palmar fascia. The radial sac envelops the two tendons of the thumb only; the ulnar the two tendons of the little finger and partially those of the ring-finger. The other tendons have, as a

[7] Deutsche Medizinische Wochenschrift, July 20, 1878.

rule, no sheaths. At about the first year the radial sac joins that of the thumb and the ulnar that of the fifth finger so that free communication is established with the synovial membrane of the wrist and palm—an anatomical peculiarity which is often demonstrated clinically by the rapid spread of peripheral inflammation to the palm, when either of these two digits is implicated. There are in addition at the annular ligament two small bursæ for the superficial tendons, the palmaris longus and the flexor carpi radialis. It is not necessary to mention in detail the six small sheaths on the back of the wrist, the most important is that of the common extensor of the fingers, beginning at the wrist-joint and extending about one third of the distance up the metacarpal bones. These sheaths being more superficial, and for the most part lying directly on the bones, are more prone to injury in sprains and fractures at the wrist.

At the ankle joint all the tendons are provided with sheaths; on the front of the foot are three—the sheath of the tibialis anticus which extends from just above the extremity of the malleolus to the scaphoid bone; that of the extensor longus pollicis, from the same level to the head of the first metatarsal; and the common sheath for the extensor communis digitorum, extending from a point about two inches above the malleoli to about one inch below the annular ligament. Behind the internal malleolus are the common sheaths of the tibialis posticus and flexor longus digitorum, beginning one-third of an inch above the point of the malleoli and extending to the astragalo-scaphoid junction, and that of the flexor longus pollicis of about the same extent.

Behind the outer malleolus is the sheath of the two peronei, beginning one half inch above the malleolus, dividing into two portions for the two tendons, and ending just behind the tuberosity of the fifth metatarsal bone. Although the normal boundaries of these sacs are about as described, when diseased they enlarge and extend indefinitely in either direction.

Primary affections of tendon sheaths may be divided into acute and chronic, the most common variety being the dry, crepitating form, from over-use or injury, most often seen about the extensors of the thumb, although in many of these cases, as Larger has shown,[1] the disease is of the ante-brachial bursa, and not in the sheaths of the tendons themselves. Less frequent is a subacute inflammation with slight swelling and local pain about the affected tendon. An acute inflammation with great effusion, has been described by Brunon,[2] but there are few supporting cases.

A more chronic or plastic inflammation, caused by repeated injury, or after rheumatic affections, or from peripheral irritation or suppuration, which causes adhesions between the tendons and their sheaths with resulting functional disability, was first described in detail by Gosselin.[3] This form is of particular interest to us, who are considering secondary affections of tendons in relation to injuries of the joints. The treatment of these acute and subacute inflammations of tendon-sheaths is, as is well known, absolute functional rest, local compression, massage, and stimulation.

Chronic disease of tendon-sheaths, characterized by slow enlargement without adequate cause, increasing in size with progressive functional weakness and deformity, most often affecting the palmar sheaths, is now considered identical with fungous disease of the sheaths, and tuberculous in character,[4] for which there is but one treatment, early and complete excision. I have, at a previous meeting of the Society, shown one of these cases—an enlargement of the sheath of the common extensor of the toes, a large tumor constricted by the annular ligament and bulging in a characteristic manner at either end. The sac was removed and found to be almost completely filled with rice-bodies. To my surprise, microscopic examination showed no sign of tubercle. In the literature of the subject, however, may be found many similar failures, although the true character of the disease was afterward proved by inoculation,[5] so that Verneuil[6] classes them as cases of "concealed tuberculosis." The patient now, nearly a year after the operation, has perfect functional use of the foot with no sign of recurrence of the disease.

It is unnecessary to describe affections of bursæ as distinct from those of the tendon-sheaths, except that many of them being superficial, are more liable to injury, with acute inflammation and suppuration. The treatment is similar—rest and compression in the early stage, excision in chronic disease, since, tuberculous or not, it is at any time liable to become so. Volkmann has shown that the fibrinous deposit in these chronic affections is a most favorable nidus for the deposition and growth of the bacillus. The diseased bursa is not essential to the functional use of the tendon, but a source of weakness, at any time liable to acute inflammation.

Enlarged bursæ in connection with tendons, are most often found in the popliteal space, and, as Foucher has demonstrated,[7] the bursa of the semi-membranosus muscle is usually affected.

Cysts in this locality, communicating with a diseased knee-joint described by Morant-Baker,[8] are of little interest in this connection. Corresponding to the subacute inflammation of tendon-sheaths is a similar affection of connective tissue about a tendon. My attention was recently called to this point in the treatment of a boy of sixteen, suffering from pain and progressive weakness at the wrist, with no previous history of injury.

All that could be made out, was a slight thickening, with local tenderness about the flexor carpi radialis tendon, at the wrist. Palliative treatment was of no avail, but recovery followed promptly after complete confinement of the hand in a metal splint with local compression and stimulation.

Another point of interest in this connection is the local pain and tenderness about the insertion of the tendo Achillis, caused by overwork or the pressure of tight shoes.

Raynal has described the arrangement of the tendon,[9] enclosed with connective tissue between two layers of fascia, and considers the affection a peri tendonous inflammation, to be treated in the manner already indicated. After rheumatic inflammation of the feet, pain in this locality is often very persistent, and when combined with thickening at the insertion of the tendon, indicates an implication of the bursa, an affection which is extremely chronic in character.

We now come to a more important application of the subject, the relation of the affections of tendon sheaths and bursæ to diseases and injuries of the joints. I have already indicated the importance of removal of a diseased bursa, which by its liability to acute inflammation is a source of danger, of the tendon-sheaths affected by tuberculous disease, which by extension may set up disease of a similar character in the contiguous joint and have outlined the treatment of the acute and sub-acute inflammations, because the same principles apply to the treatment of secondary affections, the result of sprains and fractures.

The relation of tendon sheaths to joints explains an important difference in the symptoms of persistent disability in the two joints most often injured, the ankle and knee. In the former, the indications for treatment are almost always outside the joint: pain, local tenderness, and limitation of motion. In the knee, the important symptoms are inside the joint: a slight synovitis, a

[9] Archiv. Gén. de Méd., 1882, p. 677.

thickening on either side of the ligamentum patellæ, with weakness and insecurity. Again, it is not always the deformity of a badly treated fracture of the wrist that causes the subsequent weakness, for we see cases of extreme deformity with no functional disability but the pain, stiffness, and limitation of motion of the wrist and fingers are the important symptoms. This, we may assume, is the permanent effect of injury on the tissue surrounding the joint, exaggerated in the aged or rheumatic subject.

At the wrist- and ankle-joints, with tendons of great functional activity running directly over and in grooves of the bone, surrounded by synovial sheaths, the effect of the violence which breaks the bone must cause tearing of the sheaths, effusion of blood, and subsequent inflammation of a plastic character. As in fracture of bone the amount of provisional callus thrown out is in inverse proportion to the perfect apposition and retention of the fragments, so the amount of plastic material effused in bruised and torn tendon-sheath must correspond. Yet it is the common practice in the treatment of Colles's fracture, to allow early functional use of these tendons, with the purpose of thus preventing the limitation of motion which so often follows. If we consider the proper treatment of primary affections of bursæ, complete functional rest and local compression, followed by early local massage and stimulation to aid in the absorption of effused products, it will indicate the proper treatment for these secondary affections; not early functional use, but prolonged functional rest, with early local massage and stimulation.

In old sprains about the ankle, or after fracture, we often find persistent œdema, caused I believe partly by a chronic inflammation of the tissues outside the joint and partly by impaired circulation from loss of functional use. I have, in a former paper,[1] called attention to the fact that the too early use of an injured ankle or foot causes a voluntary eversion to avoid activity, which finally results in persistent abduction, or limitation of the important movement of adduction. My attention is constantly called to these chronic sprains of the ankle, and to the entire neglect of a proper examination, which would at once show the true condition and indicate the proper remedy. The treatment usually followed in these neglected cases has been to alternate for months blistering and plaster bandages. Now, a plaster bandage applied to a joint which after an old injury is held in improper position, or when its important movements are limited by adhesions and muscular contraction, is useless and improper; but if, under ether, the adhesions are first broken up and the contracted muscles over-stretched, by forcing the foot into a position of extreme adduction or equino varus, then the plaster bandage, which rests and protects the joint, is a most useful appliance. If this preliminary treatment is followed up by massage, support, and muscular exercise, these patients, disabled for months and years, may often be quickly and completely relieved.

The same principle may be applied at the wrist joint, whenever we find an important movement restrained by muscular or fibrous contraction. It is very important that these adhesions should be forcibly broken up, and the over-correction carried to the extreme limit at one operation; gradual stretching seems only to cause pain and to aggravate the previous condition.

The principle of treatment of all these disabilities of joints is the recovery of the normal range of motion, or if that is impossible, to place the joint in the most favorable position for the performance of its function. While in the wrist joint deformity after fracture may often be disregarded, in the ankle it is of the utmost importance that the weight of the body should be transmitted in its normal relation to the foot, so that in deformities following Pott's fracture with functional disability, an osteotomy should always be recommended. In tuberculous disease at the ankle, when restriction of motion is to be expected, the greatest care should be observed to hold the foot in the line of the leg, and at an absolutely right angle with it

I have had the opportunity of seeing many of these cases, in which a slight abduction of the foot and shortening of the tendo Achillis were in my opinion the causes of subsequent pain and discomfort; for with an anchylosed ankle, the heel on the ground is the one desideratum, the fore-foot as a weight bearer being regarded as of secondary importance.

In the preparation of this paper, I have collected from the miscellaneous cases applying for treatment at the Hospital for Ruptured and Crippled during the past year, cases of sprains and injuries affecting the joints as follows:

	Adults.	Children.	
Recent sprains of the ankle	13	2	
Chronic " " "	34	11	
Disability after fracture at the ankle	9	1	
Deformity " " " "	4	2	
	60	16	
Total			76
Recent injury of the knee	7	12	
Chronic " " "	56	11	
	63	23	
Total			86
Injury of the hip	5	23	
Strains of back	20	6	
Recent sprains of the wrist	7	..	
Chronic " " "	6	..	
Fracture of wrist with deformity	7	2	
Sprains of the elbow	3	2	
" " shoulder	11	2	

In these cases are not included recent or old fractures of the elbow, shoulder, or of the patella, as they do not directly interest us in this connection. It will be noted that of the 190 injured joints of the lower extremity, 128 were adults, and 62 children; of the 50 injuries of the upper extremity, 44 were adults and but 6 children.

We may assume that the great preponderance of injury of the lower over the upper extremities has a direct bearing on the relative frequency of tuberculous disease in the two localities.

The importance of careful treatment of slight injuries is emphasized by the recent experiments of Krause,[1] who found that it was often possible to produce local tuberculosis in previously inoculated animals by spraining joints; while severe injuries, fractures and the like, healed in a normal manner. In children, from their greater susceptibility to tuberculous infection, injury of a joint is a much more serious matter than in the adult. Children recover so quickly from injury that one of the most important diagnostic points in any suspicious case is chronicity, no matter what the symptoms may be.

I regret that my time does not allow me to pay particular attention to some of the points of interest in the diagnosis and treatment of the various affections that have been mentioned.

I have endeavored to call your attention to the importance of careful treatment of joint injuries, in the first instance, and to indicate the principles of treatment in chronic and neglected cases; to the importance of local treatment after severe injuries and fractures, and to the necessity of early excision of all chronic and suspicious enlargements of bursæ and tendon sheaths.

The study of these chronic joint affections is very instructive; it teaches the importance of an accurate knowledge of the functions and anatomical peculiarities of normal joints, and as affected by injury and disease; what is to be avoided and guarded against in the acute stage; and in neglected cases the importance of treatment conducted with an object, as opposed to the routine application of remedies on general principles.

THE REQUIREMENTS FOR A DEGREE IN ARTS, AND IN MEDICINE.

THE *Sun* has been publishing a series of learned editorials regarding the subject of the requirements for the degree of A.B. in the very numerous colleges of this country which confer that distinction. It finds naturally a very great difference in these requirements and calls attention to the need of some more definite standard of what is meant by a liberal education.

This subject has been studied some years ago by the Ohio College Association, and recently by a committee of the American Academy of Medicine. The February *Bulletin* of the latter organization contains an account of the very earnest and diligent labors of its committee.

They recommend, in brief, that the Academy adopt provisionally the requirements laid down by the Ohio College Association, as expressing the minimum amount of study that should entitle one to a degree of B.A. or Ph.B. The college course, as laid down, includes Language and Literature, seventeen terms; Mathematics, five terms; Natural Science, six terms; Philosophy, four terms; History and Political Science, four terms. The course is not too severe, and is about that adopted by the smaller Eastern Colleges. It has the defect that it does not allow for substitution of more terms of Natural Science in place of Literature, and it calls for Greek, a language not required at Harvard.

The American Academy, however, has done a useful thing in calling attention to the subject on which it reports; for it seems that there are classical as well as medical colleges where degrees are gotten very easily.

Perhaps the most interesting chapter in the committee's report, however, is a letter from a prominent college president, sent in reply to a circular letter of inquiry regarding the minimum qualifications for a degree at his institution. The gentleman says:

"Your letter of the 5th is before me. I have answered in the usual unsatisfactory way which must necessarily be adopted as to such printed questions. I am impelled to say that the American Academy of Medicine has probably a larger work on its hands than it can soon accomplish within the circle of its own profession. It appears to me that it would be a great advance, one almost hopeless, however, if the students who enter Medical Schools could be required to have any sort of a degree before they are admitted. It was once stated before the Literary Club of Chicago, when such a subject was under discussion, by the President of an University, that in the eight Medical Schools in Chicago, not so many as *two per cent.* of the students had any degree at all. This used to be true of the Medical Schools in Philadelphia, years ago. I do not know that it is remedied yet. We lose a score of students every year, who have been with us one to three terms, or one to three years, and who leave us to go to Medical Schools. A poor student who took chemistry for one or two terms, and failed in that, is almost sure to write me in a year or two from some Medical School, and want his grade in chemistry, which will be *accepted by the school where he is.* I used to write to my friends in the medical faculties, of whom I had many, protesting against the reception of the standings we sent; but it was of no avail. I have seen the men whom we eliminated for poor scholarship graduated as Doctors of Medicine before their superior classmates who remained with us obtained their degrees of B.S. I beg to suggest, in no captious or cavilling spirit, that when your Academy has brought the Medical Schools of the United States up to the standard of the Colleges and Universities, the latter will need little looking after."

Of course a letter expressing such kindly criticism demanded a reply. In this it was stated that the Fellows of the Academy, being college-bred as well as graduates of Medical Schools, had the same right to investigate the methods of the one as of the other. To this the following reply was received:

"I thank you for the pains you have taken to inform me as to the purposes of the American Academy of Medicine. As it seems that the fences about the medical profession are all removed, or are so full of gaps as to be nearly useless, it would seem that an effort to build up within the profession itself an organization, such that membership in it should mean both merit and culture, would be both desirable and feasible."

THE DIAGNOSIS OF DIPHTHERIA AND CROUP.

THE ancient controversy over the identity of membraneous croup and diphtheria seems likely to take a new phase; and one, furthermore, which may revive the dual theory of the disease now practically abandoned. Of course it is bacteriology which will do all this. At a recent meeting of the Berlin Medical Society, Professor Baginsky (*The Lancet*) presented the results of a year's clinical and bacteriological observation of diphtheria in the Children's Hospital under his charge. Accepting it as established that the Klebs-Löffler bacillus is the specific organism of true diphtheria, he subjected 154 cases supposed to be this disease to bacteriological tests. Blood serum was used for the cultivations, which were carried on at a temperature of 37° C. In most cases the microbes found in association with Löffler's bacillus disappeared, and there was left a pure culture of the latter, which, in a few hours, assumed its typical and easily recognizable characters. This test was supplemented by microscopical examination of dry preparations, and, in doubtful cases, by the result of inoculation on animals.

In 118 out of the 154 cases, the specific cultures were

obtained. In 45, or more than thirty-eight per cent., the patients died. Thirty-nine of these cases were associated with paralysis, 17 with severe septic phenomena, and 44 cases required tracheotomy; while only 28 (or twenty-five per cent.) ran a mild and favorable course. On the other hand, there were 36 cases of the whole group from which the deposit yielded no bacilli, but only cocci; and it is particularly instructive to note that only 4 of these were fatal, one being a case admitted with severe paralysis, another complicated with measles and dying from pneumonia, and two developing empyema. All the rest ran a favorable course, and recovered in a few days without complications. The inference drawn by Professor Baginsky from these facts is that there are two types of disease, indistinguishable in their superficial characters, marked by a deposit of false membrane on the fauces and tonsils, and associated with fever, prostration, and swelling of lymphatic glands. The one is true diphtheria, and is caused by Löffler's bacillus; it is of far greater severity than the other, which appears to be excited by staphylococci and streptococci, and runs mostly a favorable course. Nor is the latter so remarkably contagious as the former; while he has known the bacillary disease to supervene upon and prove fatal in a child who had gone through the milder affection. So convinced is he of the value of this distinction that he has devised apparatus for conducting the bacteriological inquiry as a part of clinical investigation.

In the discussion of Professor Baginsky's paper it was asserted that the bacteriological test was not a practicable one for ordinary clinical use. Still it will probably have to be used hereafter in scientific studies of diphtheria, and especially in therapeutical statistics.

Reports of results from new modes of treatment must be supplemented by a bacteriological as well as clinical diagnosis.

There seems little doubt, from Baginsky's observations, that while some cases of membraneous croup are true diphtheria, others are not.

HOSPITAL ALUMNI SOCIETIES.

The ex-members of the house-staff of the New York Hospital have organized under the name of the Association of the Alumni of the New York Hospital. There are now medical societies composed of the graduates or alumni of Charity, Bellevue, the Woman's, and, we believe, other hospitals; there is also a Hospital Graduates' Association. These societies are all interesting and valuable no doubt, but it looks as though in time the organization of ex-internes would be overdone. A single organization, like the Hospital Graduates' Society, with branches or sections, might cover the ground and take up less of the time and expense which go with carrying on all new societies.

THE COLONIZATION OF THE PHTHISICAL.

Two or three years ago the late Dr. Paul Kretschmar, of Brooklyn, read a paper strongly urging the establishment of sanitaria near large cities for the treatment of cases of phthisis. The idea was that people of moderate means should have a place where they could go, and for a small sum get all the benefits of the best modern methods of treatment instead of staying in crowded cities or uncomfortable country boarding-houses.

Not long ago Dr. S. E. Solly, of Colorado Springs, in a paper entitled "Comparative Results of Treatment of Phthisis by Climate," gave the conclusions of several of the most celebrated authorities upon pulmonary diseases, in Europe and America, and by them furnished a very convincing proof of the great advantages of treatment in closed resorts (sanitaria) as compared with that in open resorts. In a table, entitled "Comparison between Open Resorts and Sanitariums in Low Climates," he gives the following figures:

ALL STAGES OF THE DISEASE.

	Cases.	Cured. Per cent.	Benefited. Per cent.
Open resorts in low climates.....	1,724	6	46
Sanitariums in low climates	2,443	13	27⅞

FIRST STAGES OF THE DISEASE.

Open resorts in low climates	685	5	45
Sanitariums in low climates.....	89	31½	45

A sanitarium having somewhat the objects we have above referred to has been established at Saranac Lake, in the Adirondacks. Another has been established by Dr. V. G. Bowditch, at Sharon, Mass. Various other sanitaria, adapted for comparatively wealthy patients, also exist. The fact has been established, we think, that phthisis is best treated in places specially arranged for this disease.

We have hinted before that it is time for our great public charitable hospitals to adopt the sanitarium plan. In this city over five thousand persons die of phthisis annually. In Charity Hospital one-third of all the deaths are due to the same disease. In is a well known fact that poor people who enter our city's hospitals, even in the first stage of phthisis, have but a small chance of recovery, while in a good sanitarium the percentage of recoveries is about fifty. The city hospitals should therefore establish a country annex where the phthisical patients could be colonized and receive appropriate treatment for their condition. As it is now, many good and all bad cases are transferred to Charity, to die a lingering death. This plan has already been adopted on a small scale by one of our rich private hospitals. It should be extended further.

We are having a great deal done for the chronic lunatics, to whom death is a release. There should be more done for the phthisical, for whom health, usefulness, and happiness is a possibility.

HOW MANY ARE THERE OF US?

Vital statisticians must be somewhat embarrassed in attempting to produce figures based on the total population of New York City. The United States Census for 1890 gave us 1,515,501 inhabitants. The City Board of Health, in the same year, estimated the population, July 1, 1890, at 1,631,232. The recent State Census gives the population as 1,800,891. Assuming that the Board of Health estimate in 1890 was correct, its present estimate, based on its former records, would be about 1,700,000. But taking the United States Census of 1890 as a basis, our present population would be about 1,600,000. Here is a difference of 200,000, enough to make a considerable city of itself. According to the last Census our death-rate

is about 27 per 1,000; according to another, about 22 per 1,000. It seems as though the greatest city of the Western Continent ought to be able to get nearer the actual truth in these matters than has been done.

It is probable that the Board of Health estimates, which would place our population at about 1,700,000, are nearest correct.

SOME COMMON DISEASES OF THE RECTUM.

Man, and more particularly civilized man, is distinguished from the lower animals by being constipated. By reason of this, of his erect position, and from various other causes, the rectum has become at the present day the seat of a great many unpleasant maladies. Mr. Christopher Heath, in a clinical lecture on common diseases of the rectum, gives some interesting and practical facts regarding this matter.

Though constipation is not especially a rectal disorder, Mr. Heath has a few words to say about it. He states, first of all, and very positively, that the best time for persons to have a regular movement of the bowels is at night. This rule applies, however, more particularly to persons who suffer in any way upon the discharge of fæces or who have a costive habit. The reason given is that more time can then be given to the process, that the patient is or may be undressed, and can lie down afterward and rest.

Mr. Heath tells us nothing very new regarding the treatment of constipation. He suggests that in feeble and anæmic elderly persons it is not always well to force a daily passage. He approves of enemas of water and of glycerine; and he recommends a teaspoonful of sulphur in milk as a good aperient for daily use. He further says: "The difficulty which many persons experience in getting rid of a mass of fæces which has been lodged in the upper part of the rectum and become a little inspissated and hard, can be got over entirely by pressure with the finger just beyond the tip of the coccyx. There is plenty of room between the tip of the coccyx and the anal orifice for the finger to be pressed against the rectum, and you will find that the hard motion which has lodged in the rectum is pushed out through the sphincter, and being once through it is promptly passed, and the softer matter follows easily enough."

With regard to fissures, he recommends a caustic in mild cases, and stretching or a shallow cut in severer forms.

Pruritus ani is often due to ascarides, and then salt and water enemata, with thorough purgation is indicated. Pruritus not due to parasites, he treats chiefly with lotions. A five per cent. solution of cocaine, he says, is "not a bad thing," combined with attention to the bowels and general tonics. The subject of eczema as a cause is not touched upon. There occur sometimes about the skin what are termed "rhagades."

There is hypertrophy of the skin of the anus with ulceration in the cracks between the folds, which is undoubtedly syphilitic, and should be treated very much like mucous tubercles. But, he says, you will find occasionally that there are considerable outgrowths of moist skin about the anus, which are commonly called "tabs." They are not really a disease, but are only a symptom, and wherever you see them you may be sure that the woman—for they usually occur in women—has syphilitic disease of the rectum. You should at once introduce the finger, and you will probably find ulceration of the rectum of a tertiary syphilitic character, with very likely more or less stricture."

Many cases of what is called prolapse of the rectum occur in children. There is in reality, however, no true prolapse. The trouble is caused by the presence of small polypi. These are easily and safely notched with the nail and removed.

Ordinary cases of prolapse are cases simply of debility, the child is of weak habit altogether, and the bowel has got into the way of coming down on very slight occasions. The great thing is to break through the habit. With a circular opening like the anus very little will bring down the mucous membrane through it, but, says Mr. Heath, "if you can get the mother to hold the child when it is going to have an evacuation, and to put the finger down the verge of the anus and draw on one side, and thus convert the circular opening into an elongated slit, then the mucous membrane is considerably puzzled to come down, and practically it does not prolapse. What I always promise mothers is that, if for one week they will take the trouble to do this, and so prevent the bowel from coming down, the case will probably be cured. In addition to that little manœuvre it is well, of course, to brace up the bowel by throwing in cold water with an enema syringe, both before and after evacuation, and to give the child a tonic, particularly an iron tonic."

Ordinary cases of prolapse are easily cured, but sometimes the entire end of the bowel comes down, and then the treatment is more difficult. Mr. Heath recommends the cautery. The method is to draw a series of vertical lines upon the prolapse, and then, under chloroform, to put the part thoroughly back, and with the cautery to cut two or three deep grooves in the anus itself, because in these cases it is enormously dilated, and, unless one thoroughly contracts up the anus, no power will keep the bowel within. Then, of course, one must lock up the bowels with opium, and keep the patient carefully in bed.

THE FUTURE OF THE LITTLE TOE.

Mr. R. C. Lucas, in common with the comparative anatomists, says that the little toe has got to go. It is a useless little appendage, and almost as much out of date as the pineal gland. It has already lost one of its extensor tendons. We are further told that the second and third phalanges of the little toe are, after a certain period of life, commonly found anchylosed, which is a further proof of the downward descent of this appendage. The future of the human foot would appear to be a gradual suppression from without inward of the toes, and a further strengthening of the great toe line on the inner side. That this is all that is required is abundantly proved by observing the thousands who, even at the present time, use only the great toe as a means of progression. "I was," Mr. Lucas states, "much interested some few years ago by observing the foot of one of the finest athletes of the day. He was an All-England three-quarter at football, a champion short- or mid-distance runner, and the finest football kick of his day; yet he wore a boot so narrow that only the great toe could approach near to the end of it. All this

brilliant performance was done by the great toe alone, and he showed on the running path and in the football field that swiftness, agility, and strength were, so far as the foot is concerned, centred in the line of the great toe." Mr. Lucas quotes the following clever poem, published in *Guy's Hospital Gazette*, and entitled "Digiti Minimi Decessus:"

"If thou must go, thou feeble, foolish digit,
Fain would I speed thy slow degenerating way!
I daily feel a disagreeable fidget
Whenever I've occasion to display
Thy doubtful outline, and thy form chaotic
(Born of a taste in boots, perhaps erotic).
Thou art a shock to my æsthetic sense,
And offerest no kind of recompense
In way of use; of every function shorn,
Except to act as basis for a corn.
When thou art gone I'll still maintain my grace,
Still walk erect wherever I may be;
Still I'll belong to the athletic race,
Waltz with the fair, and kick my enemy!
So *pace* Schopenhauers, and *pace* Mallocks,
When I've acquired a hypertrophied hallux,
To monodactyle type thus simplified,
Life shall be simpler too, and so—beatified.

"When future science forgets thee in thy prime,
Methinks a great mind from a northern clime
May then discuss thy remnants, and declare
He finds a true *prophetic organ* there!"

THE TREATMENT OF MYOPIA WITHOUT GLASSES.

The tendency of oculists to prescribe glasses for muscular refractive troubles of the eye is apparently increasing. Many recommend glasses for slight insufficiencies of the ocular muscles, still more advise glasses for slight degrees of hypermetropia and astigmatism. The number of spectacled children is nowadays enormous and is yearly increasing. We are not prepared to deny that the glasses thus prescribed are not needed, or that the patients are not always greatly benefited by them. Yet it seems as if possibly the thing were a little overdone. The patients are, perhaps, in a measure to blame, for few who go to the oculist for weak or defective vision are quite satisfied if they do not get a prescription for glasses at least.

We feel some interest, therefore, in the assertions of Dr. W. H. Bates (*New York Medical Journal*) that myopia can be improved by medical and other treatment, so that in some cases patients can get along without the use of glasses.

Dr. Bates's method seems to consist mainly in using atropine, giving nasal treatment and tonics. Counter-irritation over the spine or temples is also employed. The practice of using atropine for myopia is an old one, and we do not find anything especially novel in Dr. Bates's suggestions. But it is possible that good might come from a more general attempt to lessen the degree of myopia before compelling the patient to put on his crutches.

Marine Hospital on Martha's Vineyard.—The Government has accepted six acres of land at Vineyard Haven as the site of the new Marine Hospital. The tract is situated on the bluff across the harbor from the village of Vineyard Haven.

News of the Week.

New Laboratories in Chicago.—Both the College of Physicians and Surgeons and Rush Medical College have had plans perfected for spacious additions to present buildings, to be used for laboratory purposes. Space for laboratory instruction and work is sorely needed by both institutions, the present arrangement being entirely inadequate to the demands.

Health Commissioner vs. Physician.—At the last (March 7th) meeting of the Chicago Medical Society, the following resolution, signed by a large number of practitioners, was adopted: "*Whereas*, There exists a deep and wide-spread feeling of indignation at the unceremonious harshness with which many of the physicians of Chicago have been treated by the present Commissioner of Health, we, the undersigned, are of the opinion that it falls within the province of the Chicago Medical Society to institute an inquiry into the nature and cause of such dissatisfaction. We therefore ask that such an investigation be made, not in any hasty or partisan way for the purpose of defaming or glorifying the character of anyone, but in order to determine in a calm and judicial manner the rights and privileges of all parties concerned, and to suggest measures for the relief of the present discontent. We are convinced that a proper regard for the self-respect of every physician, and for the dignity and honor of a learned profession, render such action appropriate and necessary at the present time."

A Law to Regulate Embalming.—The following is the text of a bill introduced in the State Senate by Senator Smith and referred to the Committee on Judiciary: The People of the State of New York, represented in Senate and Assembly, do enact as follows:

Section I. Section three hundred and six of said code is hereby amended so as to read as follows:

§ 306. Duty of Burial. Except in cases in which a right to dissect it is expressly conferred by law, every dead body of a human being, lying within this State, must be decently buried within a reasonable time after death, unless preserved by suitable embalming, which is hereby permitted only in the following cases:

1. It shall not be lawful for any person to inject any substance into, or to embalm, any human dead body without previously having the written consent of the physician who attended the deceased in his or her last illness, or of the coroner having legal custody of such dead body; except as provided for in this Chapter.

2. No person shall inject into, or place upon, any human dead body any arsenic, or any substance or solution containing arsenic, mercury, zinc, or carbolic acid; except as provided for in this Act.

3. Nothing in this Act shall prevent the use of liquids containing arsenic, zinc, mercury, or carbolic acid for the disinfection of the bodies of persons dead from contagious diseases, by officers of any Board of Health; or for the preservation of bodies for dissection in a legalized medical college.

4. Any person violating any of the provisions of this section shall be deemed guilty of a misdemeanor, and shall, on conviction, be punished with a fine of not less than fifty dollars, nor more than two hundred dollars; or

by imprisonment not exceeding one year, or by both such fine and imprisonment.

SECTION II. This Act shall take effect immediately.

The Keeley Cure has established a weekly organ.

Guy de Maupassant, the novelist, now insane, was a morphine user. In his novel "Horla," he has described with wonderful vividness the effects of this drug.

The Cuban Degree of M.D.—The Spanish Minister of Foreign Affairs has proposed to take away the power of the University in Havana to grant the degree of M.D., thus reducing it to the position occupied by other Spanish Provincial Faculties which can only grant a license. A large petition has been sent, begging that the Government will reconsider the proposal.

An Endowment for a New Museum in Philadelphia.—The University of Pennsylvania has recently received a gift of nearly three-quarters of a million of dollars for the erection of a biological and anatomical museum to cost nearly $200,000, and a yearly endowment of $30,000 for its maintenance. The donor desired that his name should not be published until all the designs had been completed and the "Wistar Institute of Anatomy" founded; but it has transpired that the generous donor is General Isaac J. Wistar, of Philadelphia, whose uncle, Dr. Casper Wistar, was at one time professor in the medical department of the University, for whom the proposed building is intended as a memorial.

The Pan-American Medical Congress in the West Indies.—Dr. F. W. Hutchinson, of Providence, R. I., who has been appointed Assistant Secretary-general of the Pan-American Medical Congress for the British West Indies and Venezuela, is now visiting the islands of the Spanish Main in the interest of the Congress. He is vested with power to make appointments for those countries.

A Medical Club Where "Shop Talk" is Forbidden.—The Flint Club, of Baltimore, is an organization devoted to gastronomics and diversion. Its membership of thirty or more hold monthly reunions where medical talk is tabooed; all professional cares and successes are alike forgotten for a time at the portal. Whatever may have been the intention of the members when they named the club in honor of the dignified and stately Flint, the appropriateness of the appellation to the person honored is not always visible. The plainest kind of English is spoken to the guests—freely enough admitted, if they are willing to submit to the initiatory rites—and to the members who make any remarks that are not absolutely original. The etiquette of the club must be observed by guests, whether they comprehend it or not. On one occasion a visitor was called upon to speak and to hush at the same moment—and he complied by addressing the members in the sign language, and by so doing for once staggered his hosts.

The Oregon State Board of Health has adopted a rule defining a medical institution in good standing to be one requiring three regular courses, or sessions, of six months each, extending over a period of three years' time. A physician named Barwood was refused a certificate on the ground that the school from which he had graduated did not have such three years' course. He brought the case before the Circuit Court, and a decision adverse to the power of the State Board to make such distinction was rendered. On appeal to the Supreme Court this decision was overruled and the authority of the State Board was sustained. This decision will go far toward settling the disputed question of the authority of State Boards of Medical Examiners to make such rules.

Clearing up our Nosology.—Dr. G. M. Giles, of India, has done a valuable work in clearing up some errors regarding a certain endemic disease of Ceylon, Assam. He finds that the so-called beriberi, or infectious neuritis of Assam and of Ceylon, is not a neuritis but an infection due to the presence of anchylostoma duodenalis, or, as he terms it, an anchylostomiasis. Another local name for it is "kala-azar."

Sir Spencer Wells is visiting India.

Another Case of a Ramrod through the Brain.—An Australian journal gives the following case, which is nearly as remarkable as the crow-bar accident to Mr. Phineas Gage: "Robert Campbell, a young man connected with the Postal Department, was admitted to the Melbourne Hospital, with a pistol ramrod through his brain. The story of the accident is that Campbell was out shooting with a muzzle-loading pistol. While he was ramming home the charge the weapon exploded, and the ramrod, which was composed of fencing wire, with a lead plug at the end, made by the victim, was sent through his cheek across the eye, and came out at the top of his head. Dr. Harris stated that when the man was admitted to the hospital it was found that the ramrod had passed through his cheek, on the left side of the nose, into the infraorbital plate of the superior maxilla, right through the eye, going in its course through the superior orbital plate of the frontal bone, the brain, and coming out at the top of the skull, about the middle of the internal portion of the parietal bone. The wire portion of the ramrod was sticking out of the skull about six inches. Dr. Charles Ryan, assisted by Dr. Harris, trephined the skull, having first cut off the wire. When the bone was removed, the leaden base came with it, and the eye, which had been completely destroyed, was taken out. Antiseptic lotion was then syringed through the eye-socket, along the course the ramrod had taken, and by this means the wound was well washed. The night after admission of Campbell his temperature was about 110° F.; but during the next four days it came down to normal, 98.4° F., and since then he has made an uninterrupted recovery, and is now convalescent."

Exercise is a bad thing for nervous and consumptive persons who go to Colorado. According to J. T. Eskridge (*The Climatologist*), the advice often given by physicians on sending patients is: "'Go to Colorado; live in the open air as much as possible; live on horseback all day long; herd sheep or drive (punch) cattle.' The first part of this advice—'live in the open air as much as possible'—is excellent, but the remainder is simply murderous for nine out of every ten consumptive patients who go to Colorado."

Professional Manners.—S. Weir Mitchell, M.D., in his interesting sketches entitled "Characteristics," now running in *The Century*, discusses entertainingly the manners of the doctors and their influence on their patients (*Medical Age*). There is no place, he says, where good breeding

has so sweet a chance as at the bedside. There are many substitutes, but the sick man is a shrewd detective, and, sooner or later, gets at the true man inside the doctor. There are men who possess cheap manufactured manners, adapted, as they believe, to the wants of the sick-room. According to the man and his temperament do these manners vary, and represent sympathetic cheerfulness or sympathetic gloom. They have their successes and their commercial value, and may be of such skilful make as to deceive for a time even clever women, which is saying a great deal for the manufacturer. Then comes the rarer man who is naturally tender in his contact with the sick, and who is by good fortune full of educated tact. He has the dramatic quality of instinctive sympathy, and, above all, knows how to control it. If he has directness of character too, although he may make mistakes (as who does not?), he will be, on the whole, the best adviser for the sick, and the completeness of his value will depend upon mental qualities which he may or may not possess in large amount. But, over and above all this, there is some mystery in the way in which certain men refresh the patient with their presence. Every doctor who has this power, and sooner or later he is sure to know he has it, also learns that there are days when he has it not. It is in part a question of his own physical state; at times the virtue has gone out of him.

The Health of School Children.—According to Dr. Francis Warner (*The Lancet*) there is a large group of children, amounting to nearly three per cent. of the children seen, who are so far defective in make as to be usually of low nutrition when seen in school. This fact is more marked in the 36,000 children in day schools; among them twenty-three per cent. of the boys and thirty-eight per cent. of the girls who presented defects in development were noted as of low nutrition. It appears that these children are of lower general constitutional power, and tend to an ill-nourished condition under the stress of life and the many causes of mental excitement which, while they render them sharper mentally, militate against nutrition of the body and its tissues. That the amount of mental stimulus received by children does lower their general nutrition, seems to be further indicated as follows: If we divide the 36,000 day scholars into two groups of 10,200, seen in day schools of the upper social class, presumably well-fed children, we find 5.2 per cent. of low nutrition, and among the 25,800 children in poorer day schools, 3.9 per cent. The only explanation to be offered is that the upper-class children have more stress upon them than those of poorer social position.

A Rowdy Medical Society.—One of the societies which is acquiring quite a reputation for rows, says the *Weekly Medical Review*, is the St. Louis Medical Society. It would almost appear that an effort is being made to acquire a national reputation in this respect. Other medical societies, the *Review* adds apologetically and truthfully, also have their troubles, but turmoil seems to be accentuated in St. Louis.

St. Louis Medical College Commencement.—The St. Louis Medical College conferred diplomas upon eighteen young men, March 10th. The St. Louis College of Physicians and Surgeons conferred diplomas on eighty-three, March 14th. The Missouri Medical College held its Commencement exercises on March 15th. The number of graduates who received diplomas was fourteen.

The Cause of the Lesions and Symptoms in Diphtheria is the tox-albumin produced by the growth of bacilli. Such is the conclusion of recent experiments made by Dr. William H. Welch, of Baltimore.

Ether as a Stimulant at the Temperance Hospital.—*The Lancet* says a correspondent of a contemporary expresses surprise that, at a public meeting at the Temperance Hospital, it was announced that the internal use of ether is allowed in the hospital in place of alcohol. We cannot think that there is much to justify this difference. Ether-drinking is a vice which has only lately in Ireland assumed grave proportions, requiring special legislation. It is affectation to regard the use of such an agent as morally or physically better than the use of approved forms of alcohol.

The Proper Purgatives in Intestinal Dyspepsia.—Of course only the milder laxatives, and such as disturb digestion the least, are to be thought of. Rhubarb, senna, aloes, sulphur, cascara, magnesia, are among the best. A favorite combination is equal parts of pulverized rhubarb and cardamom seeds; dose, a teaspoonful. Germain Sée prefers the old formula of sulphur, cream of tartar, and magnesia, of each equal parts; Dujardin-Beaumetz, the compound licorice powder. The aloin, strychnia, belladonna, and ipecac pill is an excellent one. "The remedy," says Dr. G. B. Wood, "which we have found most effectual in the permanent cure of a disposition to the accumulation of flatus in the bowels, is an infusion made with half an ounce of colombo, half an ounce of ginger, a drachm of senna, and a pint of boiling water, and given in the dose of a wineglassful three times a day."—*Boston Medical and Surgical Journal.*

Memorial to Sir Morell Mackenzie.—Lord Calthorpe, who has had charge of the fund for the erection of a memorial to the late Sir Morell Mackenzie, has announced that the fund will be devoted to the erection of a permanent addition to the Hospital for Diseases of the Throat, which was founded by Dr. Mackenzie in 1864, and with which he was connected until the time of his death.

The Long Island College Hospital held its Thirty-fourth Annual Commencement on March 23d, and graduated a class of sixty-four.

Influenza in Boston.—The Board of Health of Boston has just issued a tabulated report of all deaths from influenza occurring in that city, between December 12, 1891, and February 29, 1892, arranged by ages, nativity, parentage, etc., from which it appears that the total number of fatal cases was 77 males and 128 females. Of these 72 were non-complicated. The 133 remaining were complicated with sixteen different conditions, the most important of which was pneumonia, giving 58. The next most frequent complications were bronchitis, 27; heart disease, 14; old age, 13; and phthisis, 8.

The Section on Gynecology and Abdominal Surgery at the Pan-American Medical Congress.—This section has been organized by the election of Dr. William Warren Potter, 284 Franklin Street, Buffalo, as Executive Chairman, Dr. Brooks H. Wells, 71 West Forty-fifth Street, New York, as English-speaking Secretary, and Dr.

Ernst W. Cushing, 168 Newberry Street, Boston, as Spanish speaking Secretary. The foreign secretaries of the section so far elected are: The Argentine, Dr. Don L. C. Maglioni Llobet, Victoria, 737, Buenos Ayres; Brazil, Dr. Don Luiz da Cunha Feiho, Rio de Janeiro; British North America, Dr. James F. W. Ross, Toronto; United States of Colombia, Dr. Don Jose M. Buendia, Calle 10, No. 212, Bogota; Nicaragua, Dr. Juan I. Urtecho, Calle Real, Ciudad Granada; Spanish West Indies, Dr. Don Gabriel Casuso, Virtudes 37, Habana, Cuba; Uruguay, Dr. Don Enrique Perèy, Uruguay 371, Montevidio.

Another Swindler.—A swindler who claims to be an old schoolmate of Dr. A. P. Gerster, of this city, is calling on physicians, selling what is claimed to be a gas-burner of his own invention, and after receiving the money therefor departs, with a promise to deliver the goods, which of course he neglects to do. He has been practising in this way in many neighboring towns, probably claiming acquaintance with other prominent gentlemen in different localities, in order that he may gain an audience.

A Large Dose of Sulphonal.—Dr. Ernst Neisser relates in the *New England Medical Monthly* for January, 1892, the case of a lad, fifteen years of age, who took one hundred grammes (about three ounces) of sulphonal at a single dose. The drug was finely powdered and was washed down with copious draughts of water, and the boy was not seen until six hours later, so that a very large proportion of the drug must have been absorbed. He slept soundly without awaking for five days, but was not in full possession of consciousness until the seventh day. On the ninth day he was discharged from the hospital in perfect health.

A Strange Law.—It is stated in the *Lancet* that a fellow of the College of Physicians is hindered by the by-laws of his College from enforcing payment of his fees in a court of law.

A Moral City.—The *North American Practitioner* of Chicago says that a manufacturing chemist of that city recently received an order for five million aphrodisiac pills.

Aluminium in the Urine.—Dr. R. Jamin has reported a case in which chemical examination of the urine showed the presence of phosphate of aluminium. It was impossible to discover any cause for this unusual excretion.

It Probably Do.—A correspondent from Rosindale writes to the editor of the *North Carolina Medical Journal* to ask: "Do blowing a harp injure the eye-sight?"

Intubation in Russia.—Dr. Jakubovski, a Russian physician, records the following as the result of his experience with intubation of the larynx: 1. Intubation is an operation less dangerous and less difficult than tracheotomy. 2. The inconveniences of intubation are: (*a*) The patient should be under the constant charge of the physician; and (*b*) the introduction and removal of the tube provokes disagreeable symptoms. 3. Secondary pneumonias follow more often intubation than tracheotomy. 4. In croup limited to the larynx and to the superior part of the trachea, intubation is the procedure necessary. 5. In a diffuse croupous inflammation of the larynx, trachea, and bronchial tubes, tracheotomy is the operation required.—*Buffalo Medical and Surgical Journal.*

Public Baths in Boston.—The *Boston Medical and Surgical Journal* states that a company, to be known as the Boston Bath-house Company, is soon to be incorporated to establish baths for the poor of Boston, following the steps of the chief European cities, and the recently established People's Baths in New York. There is already a small establishment of this kind in Boston, where, during the first year, three thousand men, women, and children made use of it. It is hoped that after the baths are established they will be self-supporting. About forty thousand dollars are needed for the establishment of the institution.

Umbilical Hernia without True Hernial Coverings.—Referring to a case of congenital umbilical hernia reported recently by Dr. Benedict in these columns, Dr. J. S. Hackney, of Uniontown, Pa., recalls a case reported by him in the *Medical and Surgical Reporter* some years ago. The child, when born, was seen to have a tumor the size of a man's fist over the umbilicus, its only covering being the transparent peritoneum, through which could be seen the intestines. There was an entire absence of the abdominal parietes for a distance of two inches around where the umbilicus ought to have been. The cord was attached to the lower margin and to the right side of the tumor. The child lived three days, having several movements of the bowels, took nourishment, but would not nurse, and died then from general peritonitis. No attempt at reduction was made, owing to the development of peritonitis a few hours after birth. The mother had been in good health during gestation, but her surroundings were such as she had not been used to. She had recently moved into a house which was cold and damp, and had had a great deal of mental worry on account of her children, who were almost constantly sick from the bad hygienic surroundings.

One Hundred and Fifty Corpses were cremated in Paris in 1891, as against fifty the year before. The municipal authorities have recently decided that the bodies of those dying in the hospitals, unclaimed by friends, shall also be cremated, so the number of incinerations in 1892 may be expected to be very large.

A Test for Butter.—It is difficult to guard against adulteration in some articles of food, except by lengthy scientific analyses. In the case of butter, chemical analysis is important; but, *en revanche*, M. Georges Pouchet, in the *Journal de l'Agriculture Pratique*, reminds his readers of Dr. Pennetier's method. A small fragment of butter is bruised between two object-glasses, and examined under the microscope with polarized light, above a selenite lamp. If the butter be pure, nothing particular is observed; but if it contains a trace of margarine or butter which has been melted, beautiful stars, bright with all the colors of the rainbow, are seen.—*British Medical Journal.*

Sir Morell Mackenzie's Fees.—It is said that the sum of $60,000 was paid to the late Sir Morell Mackenzie for his services to the Emperor Frederick. A few months before his death he received from a London barrister over $500 for the removal of an elongated uvula. It is also said that Sir Morell made application, about a year ago, for $50,000 life insurance to the Mutual of this city, but failed to pass the medical examination.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 17, 1892.

R. C. M. Page, M.D., Vice-President, in the Chair.

Discussion on the Varieties of Pneumonia and Their Treatment.—The meeting was held under the auspices of the Section on General Medicine, the chairman of which, Dr. A. Alexander Smith, occupied a seat on the platform.

Dr. E. G. Janeway opened the discussion, which was limited almost exclusively to a consideration of the abortion, the treatment, and the symptomatology in connection with the treatment of the croupous form of pneumonia. Dr. Janeway had seen several cases in which chill and other symptoms occurring in persons of the age at which pneumonia was most likely to occur, and at a season when pneumonia was prevalent, led him to believe that this disease was about to develop, and that it was aborted by appropriate measures. Of course, the physical signs had not yet shown themselves, and it was hardly possible to say positively that pneumonia would have developed, except for the treatment. Inasmuch as where the attack took its own course in some cases, the crisis came at the third day instead of at the fifth, might it not be that this was a form of abortion of the disease? Since some cases terminated earlier than others, and ran a milder course, might not early treatment abort a threatened attack? The methods which he had adopted, where he had seen the patient within half an hour to an hour after the chill, had had for their object to drive the blood to the surface, to control the heart and quiet the nervous system. Among appropriate measures were the hot foot-bath, liquor ammonia acetatis, and aconite.

As to the necessity for reducing the fever in pneumonia, he thought it depended much upon the effect it was producing upon the heart and nervous system. As to the antipyretics to be used, he still thought well of the coal-tar series, in spite of the disfavor which they had lately fallen into. It was necessary, however, to watch their effects, and to remember the apparent variability in their purity as manufactured by different chemists. Phenacetine had seemed to him to vary least in its effects, probably because of its greater purity than antifebrine, which formerly he had thought well of. In a certain proportion of cases these remedies did good, while their use was attended with perhaps less harm than cold sponging, or the cold pack. The speaker emphasized the necessity for administering whatever remedies were employed for the effect they produced, never adopting routine dosage, and never giving more than just enough to produce the desired result. Better begin with a small quantity and work up. These precautions were especially applicable to digitalis and other heart-tonics. Objections had been offered to the use of digitalis in pneumonia, but Dr. Janeway still found it one of the most reliable cardiac tonics in this disease. It required watching, however, and should be given at sufficiently long intervals to obviate cumulative action. In dosage, where sole reliance could not be placed upon the effect of the remedy, which might not follow immediately, he said it was important to take into consideration the weight of the patient, as well as the age and susceptibility, or idiosyncrasy. There were other reliable cardiac tonics, such as strophanthus, spartein, etc. Strychnia, or nux vomica, acted favorably upon the heart as well as upon the nervous system. Again, use the smallest dose which would achieve the result. Caffein and nitro-glycerine were also useful.

Dr. Janeway said he had seen six cases with recovery in which three lobes were involved. In some of these, and in other cases of extensive pneumonia in which there was danger from asphyxia, oxygen had been valuable. It tended to quiet the patient, produce sleep, regulate the heart, and prevent cyanosis. In the six cases mentioned, alcohol and digitalis were among the stimulants used.

Regarding opium, he would not use it as routine practice in pneumonia, but if it were necessary in order to allay pain, he would give it for that purpose.

As to relapses, while some had objected to the use of this term, he did not. Relapses sometimes took place after some days in spite of attempts at prevention.

Speaking of alcoholic stimulants, he said he could not oppose their use, for he had himself taken as much as seven quarts of brandy in ten days during an attack of pneumonia from which it was supposed he could not recover. The danger was in beginning their use too early.

A Varied Experience.—Dr. William H. Thomson related his experience with several methods of treating pneumonia, which had come into vogue since he began practice. At the outset of his medical career he had adopted the method recommended by Hughes Bennett, who then was waging war against blood-letting in pneumonia. He gave salines, sweet spirits of nitre, suitable food, and looked after his patients in a general way, yet his mortality was greater in New York than was Bennett's in Edinburgh. Then he tried the method of giving five grains of carbonate of ammonia every hour. Then he resorted to the German method of giving doses of thirty grains of quinine in a few cases, but soon stopped that. Then came from the same source the method of applying ice-bags, and he tried this and read a paper in which he related fifteen cases thus treated, ten of which died. After this the newspapers had much to say against an exclusive system of treating pneumonia. He had not tried ice-bags since. Then he took up treatment with antipyrin a while, but dropped that too. About this time the conviction had grown upon him that pneumonia was a systemic disease, with a local vascular disturbance like in other systemic diseases, and that it was of infectious nature. To-day there was no question in his mind that croupous pneumonia was a specific infectious fever, quite as specific as erysipelas, to which it was, he said, closely allied. The local expression was in the lung, and spread, as erysipelas did, by continuity. Like in Asiatic cholera, the management of a case of pneumonia must vary according to certain facts, and the results would vary equally according to those facts in spite of equally good treatment. Pneumonia in some localities was of a severer type than in others. That would account for Bennett obtaining better results in Edinburgh than he in New York by the same plan of treatment. Again, in the same locality, some individuals succumbed more readily than others; their constitutions were more susceptible to the influence of the disease. Healthy emunctories went far toward lessening the severity of the disease. This was perhaps more true of the intestines than even of the kidneys. General endarteritis increased the dangers, especially that of pulmonary œdema. These remarks showed, he thought, why there were and must be such various modes of managing cases of pneumonia, unless we should find a means for inducing immunity against the disease, or of combating the influence of the micro-organism which caused it. At present we had to rely on meeting the symptoms. During the acute stage he gave aconite. If there was pain he did not hesitate to go back to a mode of blood-letting, that is wet-cupping. He then waited, watching the heart, trying to ward off heart failure. For heart- and nerve-tonic he thought it wiser to combine several than to rely upon a single one, since the latter might fail until given in harmful doses. The reasoning was analogous in giving the compound cathartic pill in preference to giving only colocynth in quantities sufficient to produce the same result. He would combine nux vomica, digitalis, and strophanthus, perhaps also nitro-glycerine. The last-named drug was useful in off-setting the tendency of digitalis to produce contraction of the arterioles.

Coal-tar Antipyretics Objectionable.— Dr. Thomson was opposed to the use of the coal-tar series of antipy-

retics because of their tendency to weaken heart action as well as other muscular action. Fever was only a symptom. When the temperature was low and the heart weak, he gave full doses of digitalis combined with muriated tincture of iron. He had found oxygen very useful in cyanosis, whatever might be the explanation of its action. He was afraid of opium, and gave it only when obliged to, to relieve pain. Combined with chloral in camphor, it was less likely to produce pulmonary œdema.

Three Classes of Cases for Treatment.—Dr. R. W. Wilcox thought the remarks of Dr. Janeway had been very judicious. He had endeavored to classify his cases, and to make the treatment as simple as possible. There were at least three classes. Pneumonia occurring in a robust adult of good habits called for different treatment from that occurring in a broken-down, alcoholic subject; and that occurring in the young required different treatment from that in the old. The three classes, then, were the comparatively young, healthy subjects of good habits; the broken down, and of bad habits; and the aged. If he saw a case the first twenty-four hours, he gave aconite or veratrum, preferably the latter, hoping thereby to control the circulation and limit the extent of the lung process. He did not begin administering cardiac stimulants until there were evidences of cardiac inefficiency. If the pulmonary second sound were accentuated in proportion to the lung trouble, he felt no apprehension; as soon as it weakened and there was increased dyspnœa and number of respirations, he gave heart-tonics. He often used strophanthus and nitro-glycerine, and sometimes strychnia or nux vomica. He gave milk diet. In high fever he had sometimes used phenacetin, well guarded with alcohol; sometimes sponging with alcohol and water; in one case the ice-bag. Avoid opium as far as possible. If the pain were pleuritic the cold coil would do much to relieve it. In alcoholic subjects he obtained better results since he had started off with half-ounce doses of the infusion of digitalis with some chloral added. A single dose of sulphonal, one or two nights, was also desirable. In old and broken-down subjects the treatment should be stimulating from the first. Say carbonate of ammonia given in milk, frequently repeated; with weakened second sound of the right heart and increased respirations, add strychnia. Caffein was valuable also. He did not believe the type of pneumonia was changing, nor that locality had to do with its severity.

About Mustard, Calomel, Opium, and Oxygen.—Dr. George B. Fowler believed that pneumonia could be aborted. He believed that an ordinary case, occurring in a robust adult, did not require much treatment. He gave no alcohol until it seemed essential. He allowed food which was easily digested, but not necessarily fluid, if the stomach were not disturbed. If there was evidence of heart-failure or dyspnœa he gave digitalis. In certain cases opium was very valuable. In Bellevue it was his rule to give small doses of opium combined with calomel.

To induce abortion of a pneumonia he relied almost solely on counter-irritation. Usually he put on the strongest mustard he could get.

He was sceptical regarding the value of oxygen, but meant to try it again and use it more freely. In pyrexia he had no confidence in the so-called antipyretics, but relied on cold bags.

Thinks the Duration of Pneumonia Cannot be Shortened.—Dr. W. H. Katzenbach said there seemed to be unanimity of opinion that pneumonia was an acute infectious disease, that its duration could not be abridged, and that the treatment must be symptomatic. In other words, that it must be treatment of the patient suffering with pneumonia. In severe pleuritic pains he strapped the affected part with adhesive plaster, and avoided opium if he could. For the relief of dyspnœa, oxygen had given good results in all cases. He thought that usually its employment had been delayed too long. He had used strychnia a great deal; also nitro-glycerine to relieve dyspnœa as well as the heart. In pyrexia he sometimes used the pack, but oftener sponged with hot water and alcohol, and gave small doses of antipyretics, say of acetanilin. There was no necessity for reducing the temperature below 102° F. He was glad no one had suggested the use of poultices or the oiled-silk jacket.

Would not Give Digitalis.—Dr. Van Santvoord was in accord with Dr. Janeway regarding the possibility of aborting pneumonia Regarding poultices and the oiled-silk jacket, they tended to keep up rather than to reduce the temperature, and helped to exhaust the patient's strength. As to cardiac stimulants, he entertained the general prejudice against digitalis except where there was marked cardiac irregularity. One objection to it was that it was slow in action. He preferred caffein. Strychnia and atropia were useful.

Relieve the Right Heart, Dilate the Arteries.—Dr. Andrew H. Smith recognized in pneumonia an infective disease, one in which there was a systemic condition and also a pulmonary condition, there growing out of the latter certain difficulties with the circulation. In one class of patients the systemic affection was light, and the patient complained little and got along well, although there might be considerable lung involvement. These patients did well under almost any line of treatment which was not actually harmful. In a second class the disease was severe from the beginning; severe chill, delirium, fever, etc. They died apparently from the intensity of the poison, without waiting for the effect upon the lung. In a third class the danger lay with the circulatory apparatus. It was not so much a question of the heart as a whole, but of the right side of the heart. There was a dam thrown across the venous circulation of the lungs; there was more blood in the veins and less blood in the arteries than there should be. Formerly in this class relief was given by blood letting. The objection to this was the waste of the vital fluid. Could this not be avoided by transferring the blood from the venous to the arterial side? In order to accomplish this, the arteries must be dilated, which he thought was best accomplished with nitrate of sodium. He preferred this to nitro-glycerine or nitrite of amyl, because of its greater permanency of action. The dose was two or three grains, preferably by the rectum. Alcohol was very useful for two reasons: first, it was an arterial dilator; second, it was, in small quantity, a food which was quickly applied to the needs of the system. As to feeding, it was injurious to have the bowel distended with undigested and fermenting food; it was also injurious to give more food than the system required under the circumstances, even if it were digested and absorbed into the circulation. Acting on these suggestions, they had, during his last term of service at the Presbyterian Hospital, treated twenty three cases of pneumonia with only three deaths, which he regarded as a good showing. One of these patients was practically moribund when he entered.

Dr. Janeway, in closing, cautioned against giving food which would cause distention of the abdomen and produce pressure on the diaphragm.

The Medical Library at Washington.—On the reading of a communication from Dr. A. Jacobi, the Academy adopted resolutions opposed to the reduction by Congress of the usual annual appropriation of ten thousand dollars to five thousand, for the National Medical Library at Washington.

Antipyrin for Whooping-cough.—Dr. Feer reports eighty cases of whooping-cough treated with antipyrin; as many decigrams being given as the child is years of age, which would make a gram for a child of ten, morning and evening. He regards it as a very valuable remedy, but cannot be characterized as a specific. Whether it acts as a germicide or sedative cannot yet be definitely ascertained, but the balance of evidence inclines to the latter hypothesis.—*The Medical Press*, January 13, 1892.

Correspondence.

THE HEALTH RESORTS ON THE RIVIERA.

III.—Cannes (Continued from p. 363).

(From our Special Commissioner.)

THE PHYSICIANS OF CANNES—WINTER SEA-BATHING—A STUDY OF VITAL STATISTICS—PRESENT METHOD OF DRAINAGE—THE NEW SYSTEM OF SEWAGE DISPOSAL—INDICATIONS AND CONTRA INDICATIONS — OUT-DOOR LIFE AND AMUSEMENTS—WALKING BETWEEN NICE AND CANNES—THE REUNION CLUB—THE NEW GOLF CLUB—THE NEW CASINO—BEAUTIFUL GARDENS AND RARE FLOWERS.

The medical fraternity here is well represented by eminent talent belonging to various nationalities. Some of the most distinguished physicians hail from England. This, for obvious reasons, is as it should be. There are so few American families among the annually-returning winter residents that an American doctor would probably spend most of his time in a profound study of the attractive features of an empty office in a dear neighborhood.

The bachelors of Cannes also point with pride to the presence there of an accomplished medical maiden, named Agnes McLaren. At last accounts, Agnes was holding her own against all competitors of the sterner sex.

From the long list of doctors published in the *Annuaire des Alpes Maritimes*, 1892, the following alphabetical abridgment is selected: Dr. Battersby, English; Dr. Bright, English; Dr. Cazalis, French; Dr. Duke, English; Dr. Frank, English; Dr. Girard, oculist; Dr. McLaren, English; Dr. de Valcourt, French.

Dr. de Valcourt speaks English so fluently that his French origin would hardly be suspected. He is the Consular Agent of the United States.

Dr. Philip Frank has been a winter resident of Cannes for twenty-six years. He is far-and-away the best known, and certainly one of the most justly eminent, men in the Riviera. Dr. Frank has his office apartments in the city, but lives in the pretty villa Grandbois, some distance away. The beautiful gardens of this villa give some idea of what can be done in a horticultural way in so favored a spot as Cannes. There is an absolutely perfect system of drainage here, even to the extent of complete separation of kitchen waste from general house waste. The presence of an ample, well-cemented, and properly ventilated cesspool, quite away from the house, shows clearly enough that, provided only you have ample space, the cesspool system may be made inoffensive and innocuous.

Dr. de Valcourt is the author of the best book on the climate and medical advantages of Cannes. He is also a M.R.C.P. of London. The practitioner is a great believer in the utility of sea-baths continued all through the winter, more especially as a cure for scrofulous diseases. He has published in the *British Medical Journal*, October 27, 1888, some decidedly encouraging results. He is consequently an earnest advocate of the extensive employment of this rather shivery method of treatment. It should be mentioned that Dr. de Valcourt's cases were mostly hospital patients recruited from the ranks of the poor.

The beach of Cannes certainly looks inviting. Instead of the forbidding shingles of Nice, you have there soft and clean looking sand, a gradual incline, and even at times an angry surf. But indiscriminate winter sea-bathing does not commend itself to the average run of semi-invalids and health loungers. A severe eclecticism must be exercised in that direction, if the actual harm is not to more than counterbalance the possible good.

Cannes has no Board of Health. There is, however, the *état civil*, where a record of deaths is kept. Copies are on file at the Mayor's office. The British Vice-Consul, Mr. John Taylor, by special arrangement, is also given a transcript. For ten years the deaths at Cannes were as follows:

Table of Deaths at Cannes.

Year.	Total.	French.	Others.	Remarks.
1881..	681			Large works going on by a big land company employing large numbers of Italian workmen, *e.g.*, 5,000 Piedmontese laborers.
1882..	730			
1883..	789			
1884..	567			
1885..	482			
1886..	481			
1887..	585			
1888..	521	408	121	Influenza years.
1889..	560	420	140	
1890..	636	460	160	
1891..	576			

Based on a census enumeration giving Cannes a 20,000 population, we would have the following percentages of mortality:

	Deaths per 1,000.
1881	34.5
1882	36.5
1883	39.9
1884	28.3
1885	24.1
1886	24.0
1887	29.7
1888	26.0
1889	28.0
1890	36.8
1891	28.8

But it would hardly be fair to estimate the death-rate in that way. For, in drawing conclusions from a study of the above tables, we must remember that the actual population of Cannes is much higher than that given by the census. The latter keeps it arbitrarily below twenty thousand for well known municipal reasons (taxation in France is much higher after the 20,000 limit has been passed). At Cannes numerous Italian laborers are not counted as citizens, although any death occurring among them will be recorded against the general population. The census of 1886 gives Cannes 19,594 inhabitants, that of 1891 estimates them at 19,989.

The floating population, comprising hotel-guests, visitors, servants, and winter-villa residents, is computed by the British Vice-Consul, Mr. Taylor, at from 6,000 to 8,000. This gentleman having resided at Cannes for the past thirty-three years, and having personal facilities not enjoyed by others, is in a position to give reliable information.

Dr. de Valcourt, the United States Consular Agent, places a still higher estimate (up to 10,000), on this fleeting family of human birds of passage. There is also another circumstance to be taken into consideration, namely, that in all these French towns there is an excessively large infant mortality. In spite of its British colony, the infantile mortality at Cannes reaches from twenty-six to thirty-two per cent. of the total number of deaths.

In view of all this the normal death-rate of Cannes is difficult to fix. But it would probably not average below 28 per 1,000. This is neither very good nor very bad. But in any event it is reasonable to anticipate a considerable reduction in mortality on completion of the new system of sanitation.

The imperfections of the present system of drainage at Cannes are about to be remedied in every particular, and need not, therefore, be explained at length. A number of old water-courses, coming from distant mountain streams, run through the town. They are all more or less impure. But they do not "reek with filth," as has been given out in some quarters. The surface water from street-cleaning, rainfall, etc., runs into old-fashioned, large calibre sewer pipes. These empty through new iron and syphon-trapped conduits into the sea, at a short distance from the shore-line. The traps need daily attention, and are liable to become clogged with sand. They

are apparently quite useless. An iron lattice-work, arranged like a cage, retains the larger solids on the inland side of the traps. They are only an added complication This particular reform fails to reform.

Kitchen refuse is thrown out into the public streets just as in Nice. But there is this difference in favor of Cannes regarding its final disposition. The Niçois pay to have the garbage carried far out to sea and there dumped. The Cannois sell it to the farmers for fertilizing purposes.

A good many of the older houses at Cannes still have dangerous near-by cesspools. Quite a number of these receptacles are surreptitiously connected by overflows with the street drains. But all cesspools will soon be suppressed in every quarter of the town. On the other hand, a very fair proportion of the house and hotel sewage is already carried into drains of the new pattern. And all of it is now taken to a large collecting pipe that empties far out into the sea to the west of the breakwater. The pipe is 128 mètres from the shore. Its mouth is placed six inches below the surface of the water, and has, like the conduit itself, a diameter of 0.50 mètre.

Many of the private residences, of the villas that are on the rent list, as well as numerous hotels and boarding-houses are now equipped with irreproachable modern sanitary conveniences.

The underlying principle governing the construction of an elaborate network of sewers for all the highways of Cannes is simply the complete separation of surface waters from house drainage. The new conduits are made of specially prepared, impervious, glazed earthenware. They are of small calibre. Before being laid down each pipe is practically tested by a pressure of two atmospheres. There will thus be no immense subterranean sewers such as exist in Paris. The works will necessitate only inexpensive excavations, and the frequent man-holes and flushing tanks will insure easy inspection and a smooth working of the whole system.

The house pipes are connected by branches of even smaller calibre with the street drains. The latter run into a collecting main which empties everything far out into the Mediterranean. All soil and waste pipes are to be properly trapped and ventilated to the roof. In a word, a complete and simple system, in accordance with the most advanced English ideas, is to be established.

From the office of the Mayor a set of stringent rules and regulations has just been issued. But legislation is still needed to give the authorities power to enforce their rules At present they can only compel compliance therewith by the indirect method of bulldozing. And it is already apparent that some of the pig-headed natives do not bulldoze well. These regulations of the Mairie de Cannes bear the rather formidable title of "*Arrêté portant règlement provisoire sur l'écoulement direct des vidanges et des eaux usées des maisons aux égouts, ainsi que sur l'assainissement des habitations.*"

Cannes is not a cheap place. There are plenty of good hotels, but not many good boarding-houses. The Prince of Wales Hotel has perfect sanitary arrangements and the cleanest-looking kitchen I have yet seen in France. But I cannot enter into competition with Baedeker, who will give your readers more hotel points than you can shake a stick at, if you ever indulge in that form of matrimonial recreation.

All kinds of debilitated persons, whether old or young, do well at Cannes. But people afflicted with hereditary or acquired debility of the pocket-book will find the place unsuitable for purposes of recuperation. Per contra, plethoric conditions of that kind are quickly relieved. The air is exciting, stimulating, bracing, and tonic. It has sedative qualities only quite away from the sea.

The first, and even the second, stage of phthisis may be improved there. The third stage will surely get rapidly worse. Male and female hysterics are aggravated at Cannes, and are better off at home, where they can aggravate the family martyrs.

Torpid constitutions may be wakened into some semblance of life and enjoyment at Cannes. All strumous conditions are apt to be greatly benefited. The various forms of anæmia, and even cachectic states, and other dyscrasias, may be considerably improved. Asthmatics and bronchitics must be on their guard against the dusty winds, but with suitable precautions should do well. In a word, any invalid not too far gone, and who has enough constitution left to stand being whipped back into the health line by an exciting atmosphere, brilliant sunshine, sea ozone, or forest air, may safely spend his winters at Cannes.

One great advantage of Cannes over other Riviera stations is that you have actual forest scenery within fifty yards of your hotel To get such a scene at Nice you have to walk or drive full two miles between high walls; at Mentone, to go quite as far, and to climb till you are worn out with fatigue; at San Remo, to go somewhere else in a carriage.

The possible walks and excursions round about Cannes are very beautiful, and so numerous that no attempt will be made here to do justice to them. Grasse is only a short distance from Cannes, but I may take up that place in a subsequent letter.

Nice has so many and such varied amusements that Cannes, by contrast, is often alluded to as the dullest of dull places. "Nothing going on at Cannes," is the pet phrase of those whose jaded constitutions and dulled palates require rather more spice than mere attic salt. But it would be a great mistake to suppose that healthy recreation, convivial meetings, dances, and other social pleasures are not to be had at Cannes. On the contrary, many families of refinement and culture, who would loathe contact with the grosser joys offering at Nice, find Cannes sufficiently attractive to return there winter after winter. Read this:

"Everyone will find in Cannes what he looks for, or puts into it. The visitor may live in a boat, or through a succession of morning visits. He may either go to picnics or lie in a balcony; he may explore the mountains or hire a studio, drive a team of miniature ponies, or ride on a donkey; he may dance cotillons or sing psalms, or look for trap-door spiders; he may live on the shore or among the resinous firs on the hill; he may learn languages and play on divers instruments; he may flirt and quarrel, . . . etc., through the whole gamut of human activities, rendered agreeable by the favoring factors of sunny air and pleasant companionship."

To Mr. James Gordon Bennett belongs the credit of efforts to make coaching popular in this part of the world. Certainly nature and art have here combined to extend a permanent invitation to lovers of tally ho trips. Excellent roads running through a country beautified by resplendent sunshine that bathes all the landscape in a golden glory, ever-changing views of many-colored promontories jutting out into the green blue expanse of a shimmering sea, the whole canopied over by the pale azure of a Provençal sky, constitute elements that it would indeed be difficult to find elsewhere so happily blended. It is but natural, therefore, that coaching has become quickly popular here, and I doubt not that this pastime has come to stay.

The Réunion Coaches "Comet" and "Meteor" are good specimens of the modern tally-ho. They run from the Place Masséna, at Nice, to Cannes, forming a double service daily, Sundays excepted. Here is the time-table:

THE COMET—*Nice to Cannes.*

Out.	A.M.	*Back.*	P.M.
Nice	10.10	Cannes	2 30
Le Var	10 32	Golfe Jouan	2.55
Cagnes	10.55*	Antibes	3 04*
Val Claret	11.25	Val Claret	3.20
Antibes	11 32*	Cagnes	3.50*
Golfe Jouan	11.50	Le Var	4.13
Cannes	12.15	Nice	4.35

* Change horses.

THE METEOR—*Cannes to Nice.*

Out.	A.M.	*Back.*	P.M.
Cannes	10.00	Nice	3 00
Golfe Jouan	10 25	Le Var	3.22
Antibes	10.43*	Cagnes	3.45*
Val Claret	10.50	Val Claret	4.15
Cagnes	11.20*	Antibes	4.22*
Le Var	11 43	Golfe Jouan	4.40
Nice	12.05	Cannes	5.05

* Change horses.

Fares: Single, $2; return, $3. Box Seat: Single, $4; return, $5.

It is seen, therefore, that the fare is by no means high, and even a slender purse will not suffer depletion from a trip on the Riviera tally-ho. Anything more exhilarating and healthful than this excursion in fine weather it would be difficult to imagine. And it is only natural to find invalids and pleasure-seekers alike taking frequent runs on these comfortable coaches. It is also with pardonable pride that an American can say that America took the lead in popularizing this agreeable mode of locomotion in France.

The Réunion of Cannes, is probably the most exclusive organization of its kind on the Riviera. Captain Perceval, of the Guards, was the founder, as he is the present manager, of this flourishing club. It has been in existence only five years. Though chiefly British as regards its membership, some well-known American names appear among a multitude of foreign titles that abound there, as everywhere at aristocratic Cannes. I was, however, assured by Captain Perceval that no properly introduced American would be refused admission at the Réunion. At the present moment there are Howlands, Von Hoffmans, Harrimans, Ritchies, Winslows, Blights, and other useful or ornamental citizens of the United States at this pleasant place of private entertainment. A well-known writer, thoroughly posted in Continental affairs, says that the grounds are not sufficiently extensive to admit of all the out-door sports of some English clubs. But there are several excellent lawn-tennis courts, which are constantly occupied by the élite of Cannes society, and where some of the greatest masters of the game — the brothers Renshaw, among others—often try conclusions.

There is no club on the Continent where ladies and gentlemen of the highest standing, and of all nations, meet on such an equality, and where they more thoroughly enjoy themselves. The restaurant department is excellently managed, and the charming little breakfasts and dinners that are given during the season rank among the principal attractions of the Riviera.

Balls, concerts, and other amusements are constantly given throughout the season, and even a children's ball was recently organized. The latest innovation is the electric light, and an announcement has been made to the effect that the Société de la Lumière électrique is now in a position to supply hotels and private houses. Doubtless the owners of many villas will avail themselves of the opportunity of substituting this brilliant light for the flickering illuminations formerly in use.

A certain Grand Duke, brother of the Czar of Russia, and who had the added distinction thrust upon him of being fired out of that cold climate on account of not marrying right (*i.e.*, not according to court etiquette), lives next door to the Réunion. This distinguished person has been actively employed in the installation of the new Golf Club, which is now a *fait accompli*. The success which golf has attained at Pau and Biarritz is a sure sign of the popularity of the game. It is certainly one of the most invigorating and healthy sports ever introduced, and is as far ahead of croquet, or any of the "namby-pamby" games which have followed, as racing is above trotting. Forty golfers are already enrolled on the lists of this youthful aspirant for honors among Riviera institutions.

They have also quite recently finished a splendidly-situated and artistically-decorated "Casino des Fleurs." Concerts, theatricals, and other exhibitions will form the main features of amusement at this attractive flowery house.

One cannot take leave of Cannes without praising the rare and exquisite beauty of its gardens. Some of the villas are justly famous for their unequalled floral collections. Take the Villa Valhambrosa, for example. Such flower-beds, such varied shrubs and palms it would indeed be difficult to reproduce elsewhere. Its appearance by lamplight has thus been alluded to: "The palms then throw their multitudinous shadows on the sward, a fountain lifts a tall white column into the moonlight, and as the roses fling themselves from tree to tree, you expect to see, dancing among their ropes of flowers, the elves of some 'Midsummer Night's Dream.'" Good-by, Cannes. Remember:

"Here the spring is longest, summer borrows months beyond her own;
Twice the teeming flocks are fruitful, twice the laden orchards groan;
Hail, thou fair and fruitful mother, thus I dare to wake the tale
Of thine ancient laud and honor. . . ."

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE DEBATE AT THE PATHOLOGICAL SOCIETY ON PHAGOCYTOSIS AND IMMUNITY—ADDRESSES BY DR. BRISTOWE, DR. WILLIAM HUNTER, DR. SIDNEY MARTIN, DR. A. E. WRIGHT, DR. J. G. ADAMI, AND MR. T. J. BOKENHAM.

LONDON, March 5, 1892.

THE discussion at the Pathological Society on phagocytosis and immunity was resumed on Tuesday evening last. Dr. Bristowe opened the adjourned debate. He said the resistance of the body to the invasion of infective diseases was provided for in various ways, viz., mechanical, as the opposition of the skin and mucous membranes; inflammation with subsequent encapsulation or suppuration; active warfare, or phagocytosis; unfitness of soil, etc. Should the infective principle succeed in getting past these first barriers, they would enter the system along the vessels (vascular or lymphatic) as far as the first group of glands. He thought that cure occurred by the infective principle getting beaten at the mucous membranes or at the lymphatic glands. These modes of cure, however, would not include the cure of the exanthemata after their generalization, and it was in these cases especially that immunity most frequently arose. Dr. Bristowe then contrasted various types of infective disease. Local skin tubercle, or lupus, he said, seemed to prevent general tuberculosis instead of producing it. In diphtheria and typhoid the chief symptoms were associated with the local lesions rather than with the generalized poison, which, as a rule, produced its effects after the subsidence of the local lesion. With small pox and the other exanthemata the conditions were wholly different. In small pox, immunity seemed to be acquired in the earlier stages of the disease, as it was remarkable that while the pocks were developing the poison from them was not absorbed by the body. By vaccination the generalized disease was produced which gave immunity, and this was comparable to the invasion period of variola; but he could not say how the immunity was produced. He suggested that it might be possible to avoid the local ill-effects of vaccination by injecting the lymph deeply into the tissues or into the glands. He agreed with Dr. Sanderson's views of phagocytosis.

Dr. William Hunter followed in a speech of some length. He said that before discussing the probability of one or other doctrine, it was well to have the facts clearly before our minds. These were briefly as follows: in non-protected animals virulent bacteria inoculated subcutaneously produced little or no local change, grew un-

hindered, and caused general infection; in protected animals inoculation of the same bacteria was followed by a local leucocytosis at the point of injection, a certain degree of inflammation was set up, and general infection was prevented. In virtue of some change in the body, that which was formerly capable of setting up a general disease could now only set up a local affection. What was the nature of this change? On the one hand, we had the bacteria with their powers of forming poisons, viz., toxins, toxalbumins, and proteids. On the other hand, the means which the organism had of protecting itself were of a twofold character. In the first place, there were the cells, and especially those free lances of the body, the wandering leucocytes, and, in the next place, apart altogether from the action of living cells, the plasma and serum of the blood was now known from experiments to possess antibiotic powers when withdrawn from the body, bacteria being killed after a short exposure to their action; but little was known of the substance or substances in plasma or serum to which this bactericidal action was due, further than that they were proteids. He thought the doctrine of phagocytosis had greater claims than the one which was opposed to it. By revealing to us, as it had done for the first time, the potentiality possessed by cells of themselves combating the attacks of virulent microbes, it had added much to our knowledge of the means by which infectious disease was combated. The theory of the bactericidal action of blood-serum, to which so much importance was attached by the opponents of the phagocyte doctrine, was itself the direct outcome of the attention drawn by Metschnikoff to the action of cells. So far from being antagonistic, the phagocytic and the humoral doctrines mutually supplemented and supported each other; both recognized the existence of antitoxic and antibiotic substances in blood-serum and plasma. If a choice had to be made between the two, the one we could least do without was that which attached a preponderating importance to the cells of the body rather than to the fluids, to the action of the cells rather than to the products of that action, to the agents rather than to the instruments. On both views the final nature of the change, whether in cell or in product, was unknown. The change in the cell, though, must necessarily precede that in the product, and the doctrine of phagocytosis directed most attention to the cells; he thought, therefore, that that doctrine had claims on our support greater than any teaching that would, even temporarily, draw our attention away from the cell to the fluid in which it lay, or that would exalt the product at the expense of the producer. In the last place, he claimed for the phagocyte doctrine that in attaching special importance to the action of certain cells—leucocytes of blood, cells of spleen, and lymphocytes generally—it drew attention to facts of wide physiological importance, viz., that it was precisely those cells which governed, in a special degree, the constitution of the plasma and blood-serum. Dr. Hunter discussed in detail the action of the spleen, and said that experiments showed that the well known destructive action on the blood of toluylendiamin was in a special degree dependent upon the presence of the spleen; in the absence of that organ rabbits could tolerate without the slightest effect about twice the dose of the poison that would otherwise suffice to produce recognizable changes in the blood.

Dr. Sidney Martin said the question might be studied in two directions, viz.: (1) as to what rendered an animal naturally immune to disease; and (2) as to how experimental immunity could be produced. The latter was the better method of research. He observed that a bacillus, whether attenuated or virulent, acted by means of its chemical products. In the case, therefore, of Pasteur's anthrax experiments with sheep, it must be said that immunity was produced by means of the chemical products of the attenuated bacilli, and yet the virulent bacillus which produced the same products did not kill the animal. Its natural growth and activity had been inhibited. How could this be explained? Part of the explanation appeared to be that the inoculation of the attenuated virus accustomed the animal to the specific chemical poison of the bacillus. Several instances of acquired tolerance of poisonous doses of drugs were known in pharmacology. Dr. Martin described some experiments which showed that a certain degree of tolerance to virulent anthrax bacilli might be established in animals by means of the chemical products of the micro-organisms. He thought there was something beyond phagocytoses in the question of immunity.

Dr. A. E. Wright gave an account of some researches which he had made in continuation of some by the late Dr. Wooldridge and by Mr. Hankin. In 1888, Dr. Wooldridge had described a method of "chemical protection" against anthrax; this was produced in rabbits by the administration of tissue-fibrinogen. Mr. Hankin had adopted the term "defensive proteids" for the albuminous substances in which protective chemical properties were supposed to be resident, and he grafted the idea of a bactericidal power on to the more generic conception of a defensive proteid. Mr. Hankin had observed that a protective substance ("alexin") could be extracted from the spleen of the white rat. Dr. Wright said he had repeated Wooldridge's experiments with a view of isolating the constituent to which immunity was due. He found that sterilization by means of a Chamberland's filter might with advantage be substituted for the method of heat sterilization. He found, as Wooldridge had done, that anthrax could be got to grow in tissue fibrinogen solutions; the effect of tissue fibrinogen was, therefore, clearly not due to a bactericidal power. Dr. Ruffer had suggested that tissue-fibrinogen might act as a cell-stimulant, and he had himself found that its injection was followed by a remarkable increase in the number of leucocytes. Dr. Wright then alluded to a paper by Horbaczewski on the physiological effects of nuclein. He had himself shown that nuclein was a constituent of tissue fibrinogen, and since Horbaczewski proved that the administration of this nuclein resulted in the production of a leucocytosis, he naturally turned to investigate whether the protective effects of a tissue-fibrinogen solution could be obtained by an administration of its nuclein moiety alone. He anticipated that he should reap the advantage of an exact dosage, and also that of obtaining aseptic solutions with greater facility. He had only just begun to investigate the matter, but had already been able to satisfy himself that a very remarkable prolongation of life resulted from the administration of the nuclein before an anthrax inoculation, and that this prolongation of life was associated with an increased leucocytosis. He thought that Mr. Hankin's alexin was the same thing as Wooldridge's tissue-fibrinogen, or, at any rate, that it could not fail to be contaminated with it. He pointed out that the nuclein with which Horbaczewski conducted his experiments was prepared from the leucocytes of the spleen. With regard to Mr. Hankin's observation, that alexin was found only in the spleen of the relatively immune white rat, this might depend on a greater development of the adenoid tissue of the spleen in the white rat, for it was well known that the spleen played an important part in the conflict of the organism with the micro organisms of disease. A greater development of adenoid tissue would go hand in hand with a larger percentage of tissue-fibrinogen in the extracts. The newer development of the Metschnikovian doctrine, he said, aimed at reconciling the opposing schools of phagocytists and humoralists, by assuming that the disintegration products of the white corpuscles played a part in the conflict of the organism with infective disease. Each of these chemical disintegration products might possibly act in a protective manner by virtue of either a chemiotactic power, a bactericidal power, or a stimulating power. Dr. Ruffer had shown that tissue-fibrinogen solutions had a positive chemiotactic power. With regard to the bactericidal power of tissue fibrinogen, he did not think the question had finally been decided in the negative.

It had already been seen that tissue fibrinogen possessed powerful stimulating properties. He thought tissue-fibrinogen and nuclein might be regarded as cell-manures, for by whatever method these substances were introduced into the organism, they were invariably found to produce a leucocytosis.

Dr. J. G. Adami discussed the research of Klemperer and Klemperer upon pneumonia. These observers had shown that immunity (generally only temporary) against pneumonia could be bestowed upon susceptible animals by introducing into the tissues the sterilized products of the pneumococcus. Immediate immunity could, however, be produced by injecting the blood-serum of a "protected" animal into the veins of a susceptible animal. Evidently, therefore, some substance was present in the blood-serum of an animal made immune—a substance not present in the sterilized fluids of the pneumococcus. The bacterial products, therefore, did not of themselves bring about immunity, but through the febrile reaction some other body having immunity-conferring properties was gradually developed. The phenomena of infection and immunity were evidently chemical at base; certain substances were produced by the bacteria on the one hand, by the organism on the other, whose action was of a chemical or a chemico-physical nature. How was this action exerted within the body? Were bactericidal and antitoxic substances normally free in the blood, were they developed within special cells, or were they generally distributed throughout the tissues? In the first place it could not be too strongly insisted on that their presence in blood-serum was no certain indication of their presence in blood-plasma; blood-serum and blood-plasma exhibited marked differences in their characters, and nothing was more marked than this difference in the bactericidal powers of the two fluids. While bactericidal and antitoxic substances might appear or be developed in the cells forming many of the tissues of the body, it had yet to be proved that this could hold good to any extent. We were still without proof that, save in the case of organs formed largely of leucocytes and potential phagocytes, the tissue could have powers comparable to those possessed by the serum and body fluids. We were therefore driven to the conclusion that the difference between serum and plasma depended upon an alteration in the condition of the white corpuscles, and that the leucocytes were a most essential factor in the production of immunity. As to the way in which the leucocytes acted upon the bacteria, he could not help being impressed by the fact that the more perfect the methods employed, the greater was the phagocytosis observable in the course of resolution of disease. He concluded that, even though leucocytes had other methods of acting upon bacteria and their products, phagocytosis was a most important—probably the most important—factor in the production of immunity. We must look to the parent-cells rather than to the free, motile leucocytes, to explain continued powers of resistance to bacterial products on the part of leucocytes, the development of increased resistance, the development of immunity.

Mr. T. J. Bokenham gave an account of some investigations on erysipelas, and remarked that the results of these would have to be explained before the question of the causation of immunity could be settled. The inoculation of a virulent culture of true streptococcus erysipelatis into a rabbit's ear produced a typical spreading erysipelas without pus formation, though the lymph, while the process was advancing, was very rich in leucocytes. If some of this lymph were injected into a guinea-pig and into another rabbit, the latter would contract a disease in every respect similar to that in the first rabbit, but nothing would happen to the guinea-pig. The virulence of streptococcus erysipelatis, also, varied under different conditions. If a culture too attenuated to produce the disease in a normal rabbit were injected into one in which a simultaneous intra-peritoneal injection of a sterilized culture of bacillus prodigiosus had been made, typical erysipelas would appear at the point of inoculation. In this case, a rabbit which was immune to an erysipelas of a low virulence was made susceptible, and inoculation from it to a normal one would produce the typical disease in the second; by continuing the process through successive rabbits, a very virulent form of erysipelas could be produced in which a highly infective disease occurred with generalized symptoms, though no reaction occurred at the point of inoculation. Here, undoubtedly, the local cellular infiltration seemed to have played some part in the localization of the disease. If a rabbit vaccinated against the bacillus pyocyaneus were inoculated with streptococcus erysipelatis, a general fatal infection occurred without local reaction at the seat of inoculation, but blood from this rabbit could only produce the local disease in a normal rabbit. Association of attenuated erysipelas with a common mould increased the virulence of the streptococcus, both generally and locally.

A Philosophical Testator.—The following is sent to us by an old friend, and possesses some psychological phases which are amusing and suggestive:

"Will of Alexander Campbell of Richmond, Va.

"In the name of God, Amen.

"I, Alexander Campbell, being in my perfect senses, do make this, my last will and testament.

"As to my worldly estate, I give it to my wife, to dispose of as she thinks fit, recommending to her affection and care, in all situations, my dear children.

"For my soul, it is not mine to dispose of, if I have any; and if I have none, I have none to dispose of, and so, either way, the disposition seems to be needless.

"Neither is it necessary to bequeath my body to the earth from whence it came, since it is very certain to go thither, whether I bequeath it or not.

"I hope that no tombstone will be erected over me, because it will merely hinder something from growing on the spot, and, as lands now sell, it is a pity to lose so much of the earth's surface, which may be used for the sustenance of the living. If all men had tombstones erected over their graves, the earth would, in a few centuries, become one entire pavement.

"I hope for nothing, because I fear nothing. I am very certain that I am a material being, the nice combination of whose parts produces the effects of walking, speaking, volition, and other acts common to animated beings.

"Since this material being is destroyed, I have no doubt that it perishes, as far as matter can perish; that is, the form, texture, and peculiar arrangement of the body are destroyed, but the parts, principals, or seeds, which compose it, do not perish; they assume new forms by new combinations and the addition of new matter. Thus the

world eternally progresses. Nothing comes into existence but from something, which has previously perished or died.

"These few opinions I give to those, who shall read my will, that they may consider upon them, and determine whether the priests of all countries have not made a job of immortality and its long train of absurdity.

"I bid a very affectionate farewell to the world, not knowing what sort of being it will be which may spring from me.

"Written with my own hand, November 27, 1795.

"ALEXANDER CAMPBELL."

Contagiousness of Influenza.—Dr. Richard Sisley has recently published a little work on "Influenza," in London, in which he argues strongly for its contagious nature. He contends the beginning of a wide-spread epidemic is always announced by the occurrence of a few isolated cases, that the disease follows the lines of trade and travel, and that prisoners, asylum inmates, and other isolated communities usually escape from the disease, even when it is raging all about them outside of their enclosures. Dr. Sisley's views appear to have found ready acceptance, for only a few days ago a magistrate in Dover fined a number of sufferers from influenza £5 apiece for appearing in public before they had recovered from the disease. It's pretty tough to have the grip and then be fined $25 besides, just on theoretical grounds.

Higher Education for Women.—The Smith College girls are now on a tour giving whistling and vocal concerts for the benefit of their gymnasium.

The Treatment of Ozæna.—Dr. Meijer regards the treatment of ozæna by means of nitrate of silver spray as superior to all other means. He first packs the anterior nares with dry cotton for twenty to thirty minutes, to remove crusts and mucus. The tube of a spray apparatus (pulvérisateur) is introduced well into the cleansed nostril, and ten or twelve drops of a two per cent. solution of silver are sprayed in, care being taken not to moisten the skin or anterior mucous membrane, which is apt to bring on headache, flow of tears, and other disagreeable symptoms. The strength of solution is increased daily, until at the end of four days a fifteen per cent. solution is employed, at the end of eight days a twenty-five per cent. solution which is continued with for a week. Now the application is to be made only every second day, and treatment continued until crusts cease to be formed, which will be a matter of a few weeks only, in cases which under old plans of treatment lasted two or three years.—*L'Union Médicale du Canada.*

A NEW METHOD OF ARTIFICIAL RESPIRATION IN ASPHYXIA OF THE NEW-BORN, WITH CASES.

By W. E. FOREST, M.D.,

NEW YORK.

The importance of employing the very best method of artificial respiration in a case of profound asphyxia in the new-born can hardly be over-estimated. All the possibilities of a human life may, in such a condition, rest in the hands of the attending physician, and his skill and perseverance, or the lack of it, will determine the fate of the new life. An incident given by Professor R. A. F. Penrose, of Philadelphia, illustrates so graphically this point that it may with propriety be introduced here.

"Thirty-five years ago," he writes, "the wife of a young physician was confined with her first child, under the care of a celebrated professor of obstetrics. The labor was complicated and tedious; the patient during labor and after was in great peril, demanding the entire attention of her medical attendant. The child when born was apparently dead. The old professor said to the young doctor-father (the mother was unconscious): 'Doctor, cut the cord and take the child away; it is dead, and your wife's condition claims my whole care.' The father separated the child, carried it into the next room, and placed it upon a bed. He then went back and again asked the professor if he was sure the child was dead, receiving again a positive opinion that the child was dead, and that all attempts to revive it would be useless.

"The father returned to his dead baby, and having nothing to do, in a wild, hysterical, utterly helpless sort of way, began artificial respiration (mouth to mouth). Half an hour passed, with no results; the agonized father continued his efforts; an hour passed, but the infant seemed as hopelessly dead as it was before artificial respiration was commenced. The man's emotional paroxysm began to subside, and he began to realize that he was literally wasting his breath; still he did not desist. Suddenly he was startled at a slight, apparently spontaneous movement on the part of the child; with renewed energy he continued his labors, and in a short time normal respiration took place, and to his extreme felicity, and the astonishment of the medical attendant, the child was saved. This happened thirty-five years ago; the great professor is dead; the doctor-father (my friend and patient) is dead; but the child, called back to life by the hysterical blowings of an agonized father, hopelessly practised for the very long period of perhaps an hour and a half, now a grave, mature man, still lives, the comfort and solace of the mother who that day so nearly died in giving him birth."

This incident contains the elements of both a sermon and a romance, and illustrates graphically the importance of skill and perseverance in treating such cases.

Cases of asphyxia neonatorum requiring treatment naturally divide themselves into two classes: 1, Those that can be restored by simple measures that excite reflex action; 2, those that absolutely require ventilation of the lungs through artificial respiration.

The first class of cases are by far the most numerous, and the methods of treatment barely need mention. Slapping the child, dipping it alternately into cold and hot water, brandy or ice put into the rectum, blowing in the face, tickling the fauces with a feather—any or all of these means may succeed in nine out of ten of the cases of asphyxia of the new-born. But in the tenth case all such measures are wholly futile when used alone, and proper artificial respiration can alone succeed. These latter are the only cases that require scientific treatment. In these profound cases of asphyxia it is absolutely necessary that air shall, by mechanical means, be forced into the lungs and forced out again for a variable length of time, so that the blood will receive enough oxygen to keep up the functions of life.

There have been no less than nine methods of artificial respiration advocated as useful in these cases; namely, Hall's, Howard's, Sylvester's, Pacini's, Bain's, Schuckling's, Schuller's, Schroeder's, and Schultz's; to which number this paper will add another distinct method. Of the nine above mentioned, only three can be shown by careful trial and experiment to be of any practical service in asphyxia of the new-born. It may be well first to clear the field of the useless methods that have been heretofore accepted more or less widely, before going further.

Some of these methods, like Howard's, for instance, depend upon the resiliency and elasticity of the lungs for their efficiency. Such methods of respiration are of use in cases of asphyxia from drowning or hanging, and it has been supposed that they are equally as effective in asphyxia neonatorum. But it must be borne in mind that in the asphyxiated new born the lungs are in a state of complete collapse; that there is no resiliency, and can be none until it has been slowly produced by forcing air into the lungs; and that therefore such methods as Howard's are useless.

Champney's careful experiments on the cadavers of dead-born infants proved that such methods could not overcome pulmonary collapse. Another method that has been widely advocated and practised, and yet is utterly useless, is Schroeder's. At a recent meeting of the New York Academy of Medicine a physician present claimed that this method was most efficient, and put it forward as original with himself. In both claims it will be seen he was mistaken.

In Schroeder's well-known method the child is held on the palms of the operator's hands, one hand supporting the child's buttocks and legs, the other its back and head. In this position the child is alternately doubled forward and then straightened. Inspiration is supposed to be induced, in this method, by bending the child's body a little backward into the position of slight opisthotonus, so that the diaphragm may fall, the ribs be raised, and air thus be drawn into the lungs. A moment's reflection will show that this movement produces exactly the opposite effect from what is intended. In the position of slight opisthotonus the recti abdominalis muscles, extending from pubes to ribs, are put upon a stretch and the ribs are drawn down and backward, thus lessening the thoracic diameters instead of increasing them. At the same time the shoulders are dragged down by the hanging arms, instead of being raised as in the Sylvester method. Air, instead of being drawn into the lungs, would thus be driven out if it were there. The movement for forcing out the air by folding the child forward upon itself, so as to force up the diaphragm and force in the ribs, is theoretically right, but as there is yet no air in the lungs, the movement is needless. In other words, Schroeder's meth-

od consists of two movements for expelling air from the lungs and none for forcing it in. Champney's experiments proved conclusively that the method is useless, that the theory is fallacious, and whatever good results may have seemed to come from its employment must have been due to reflex influences, in cases of slight asphyxiation.

Champney found by experiment that there were only three methods of artificial respiration that could introduce an appreciable amount of air into the collapsed lungs of a new-born infant, namely, Sylvester's well known method, Schultz's "swinging method," and that by introducing a catheter into the trachea and blowing in air directly from the mouth or the bellows.

It will be well to briefly review these methods, their advantages and disadvantages, in order to compare them with what will be described later as a new method, in order to determine if the latter has any advantages over the former.

The Schultz, or "swinging method," is the latest and most fashionable method (for there are fashions in medicine as in everything else). In this method the child is held with the fore-fingers of the operator's hands hooked into the infant's axillæ on each side ; the remaining fingers clasped across the child's back, so as to offer a support ; the head steadied between the operator's wrists. The operator bends forward and the child is held in the vertical position, with the feet near the floor, and the whole weight of its body on the fingers beneath the axillæ. This is the first or inspiratory movement. In this position the lifting force is beneath the outer ends of the clavicles and they, together with the humeri, are raised. The muscles extending from the shoulders to the ribs are made tense, and the ribs are lifted, thus increasing the antero-posterior and lateral diameters of the thorax. At the same time the weight of the liver and abdominal organs draws down the diaphragm ; thus the vertical diameter is increased and air is drawn in to fill the lungs.

In the second movement, that to expel the air from the lungs, the operator swings the child forward until his arms are horizontally in front. The motion causes the child to double up anteriorly, so that the legs and buttocks fall over upon the front of the child's thorax. The weight of the abdominal organs now press the diaphragm up; the tension being taken off the clavicles the ribs sink in, and thus the air is forced out of the lungs. At the same time any fluids that may have been drawn into the mouth and trachea will run out. It would be well to put the child in the position for expiration first, not to expel air, which has not yet entered the lungs, but to expel fluids and prevent their being drawn into the lungs by the inspiratory position.

Schultz recommends that after ten or a dozen of these movements the child should be dipped into hot water in order to restore heat ; then the movements may be resumed. This method is very showy and effective in some cases, but is open to many grave objections. In the first place, it causes a great loss of animal heat from the moribund infant. When one dips the hand into warm water and then waves it through the air of a moderately warm room he becomes aware that the loss of heat by the evaporation from the surface of the hand is very much more rapid than when the hand is held quiet.

Arctic explorers find no difficulty in withstanding a temperature of seventy or eighty degrees below zero if there is no wind. But at a temperature thirty degrees higher, if the wind is blowing, even moderately, the loss of vital heat is so great that they become quickly benumbed.

The reason for this is evident : when the wet hand is moved or the wind blows on the body, the layer of warmed air next the skin is constantly displaced, and more animal heat is abstracted by the fresh air coming against the surface.

Now, when the naked body of an asphyxiated infant is taken out of warm water and waved through the air every requisite for the rapid abstraction of animal heat is provided. As the circulation of the blood is almost at a standstill, and vital processes are at the lowest possible point, there is no provision for supplying animal heat when once lost. If these manœuvres were to be kept up for only a few minutes, no great harm might be done, as far as the loss of heat is concerned, but in a bad case efforts must be continued for one or two hours, and during that time the loss of heat must be very great and amply sufficient to quench the feeble flame of life.

This loss of vital heat is not an unimportant matter. It is well known that in order to keep life in premature infants a continued high degree of external heat is necessary. A single cooling of the surface may be fatal in such cases. Cooling the surface is just as dangerous in asphyxia neonatorum.

Again, the Schultz method should not be employed, because it is too rough a method : It causes a shock to the nervous system that may be fatal in a bad case. In this method, at the end of the expiratory movement, the abdominal organs are thrown with a sudden push against the diaphragm ; this may make sudden pressure against the heart or upon the cœliac plexus of nerves, and, from shock, stop the fluttering heart. Whatever the explanation, the fact remains that these movements in cases of very feeble children will stop the action of the heart. Evidence from cases mentioned in this paper will be given later on this point.

Professor William T. Lusk in his work on obstetrics commends the Schultz method, but says if the child is very weak the method may by its violence entirely stop the heart's action.

Now, we claim that if the Schultz method is not suited to the worst cases it should not be used at all. If the case is such that it can be restored by reflex irritation, then the Schultz method is not needed ; and if it is a very grave case, so that artificial respiration is imperative, then only the best and safest method should be used.

Champney, in his experiments on the cadavers of the dead-born infants, found that the inspiratory movement in the Schultz method was very violent. He noticed in many cases that at the end of the inspiratory movement a hissing sound was heard. This was caused by the air being forcibly and suddenly drawn into the anterior mediastinum along the outside of the tracheotomy tube. This must have been due to the violence of the inspiratory movement. This result was not observed when the Sylvester method was employed, although this method was just as effective in drawing the air into the lungs.

Again it is claimed that the Schultz method is the only one that causes descent of the diaphragm, and thus brings this factor into play in drawing the air into the lungs. This claim is true, but experiments show that descent of the diaphragm is of very little consequence in introducing air into the lungs in a case of a dead-born child. Champney's experiments were conclusive on this point.

From the above it will be seen that the Schultz method is faulty, because it causes rapid loss of animal heat from the child, and is so violent as to cause fatal shock in bad cases. It has no advantage over the Sylvester method, as in both cases inspiration must be brought about by dragging up the ribs and sternum through the muscles running from the shoulder to the ribs ; and expiration results from the lowering of the ribs and sternum, thus lessening the diameters of the thorax.

The Sylvester method is so well understood that it simply needs mention. The child lies on its back with the shoulders raised slightly and supported by a firm compress ; the head inclines backward. The operator raises the child's arms above its head and draws on them until the ribs are raised and air enters the lungs. Then the arms are carried down against the thorax and pressure made to expel the air. This method is far more safe and equally as effective as the Schultz "swinging method." Champney determined that about the same

quantity of air was drawn into the lungs and expelled by each of the two methods, and that the Sylvester did not tend to cause lesions in the anterior mediastinum, such as were found after the use of the Schultz method.

In the Sylvester method a much greater amount of air is drawn into the lungs when the arms are everted than when they are inverted; this is due to the greater tension put on the pectoral muscles when the arms are rotated outward.

Another effective method for ventilating the lungs in the new-born asphyxiated is by the use of the catheter carried down into the trachea, through which air is blown directly into the lungs from the mouth or the bellows. This method is highly commended by Lusk, Polk, and many others. It is certainly effective, as anyone can demonstrate for himself on the cadaver. On introducing the catheter and gently blowing air through it the diaphragm will descend very considerably, and the ribs will rise. A dissection will disclose the fact that the collapsed air-cells have been distended by this process.

While this method is effective it does not seem to be the best or the safest method. In the first place, it is not easy to introduce the catheter through the mouth into the larynx of an asphyxiated child, even though it may be claimed to be a very simple matter.

Again, there is more or less danger of injury to the vocal cords in pushing a catheter between them. Consider how small and delicate these cords are in an infant and the consequences of a rupture of these organs. It would seem that no one but a laryngologist should be entrusted with so delicate an operation; certainly an accoucheur, exhausted by attending a difficult labor, is not the best person to carry out this manœuvre. Again, if the catheter fits the larynx at all snugly no air can escape beside it, and thus the operator may easily put too much pressure on the delicate air-cells of the lungs. In all cases of blowing into the lungs there should be an escape provided in order to prevent undue pressure. Again, as the catheter is usually employed no efforts are made to increase the diameters of the thorax by raising the ribs and sternum. This work has to be done by pressure of the air from within, as the air cells cannot be distended except as room is made for their distention through increased thoracic capacity. In other words, all the force is *vis a tergo*, and none of it *vis a fronte*. It would be safer to combine these two forces in one method.

Again, the introduction of the catheter is entirely unnecessary, as air can be blown into the lungs without its aid (as will be shown later), and therefore an act of this kind is unjustifiable.

Having thus briefly touched upon the useful methods of artificial respiration in the new-born we come to what we may venture to call a new method. In speaking of it as a new or novel method it is implied, simply, that this method has not been described heretofore, so far as can be ascertained.

The method is as follows: When it is evident that the asphyxia is so profound that reflex irritation will not remove it, and that artificial respiration is necessary, the child is first laid for a moment on its face, head a little lower than the pelvis, and pressure is made upon its back to expel any fluids that may have been drawn into the mouth and trachea. Then the child is placed in a sitting position in a common wooden pail, half full of hot water, so that the water comes up to or just above the child's heart. The operator's left hand grasps the child's wrists or hands, the child's palms being to the front, so that when its arms are raised they will be rotated outward (see preceding page for reason). The operator's right hand supports the child's back across the shoulders, with the child's head fallen back and resting in the crotch between the thumb and finger of this hand.

The infant being in position, the first movement is that for getting air into the lungs. The child's arms are carried steadily upward and a little backward by the operator's left hand, until the weight of the body comes upon the shoulders, the back steadied by the operator's right hand, the head supported between the thumb and forefinger. In this position the child's arms are drawn up and rotated outward, and the muscles extending from shoulders to ribs made tense. Thus the ribs are raised. As the child is in the sitting posture the abdominal muscles are relaxed, and thus do not tend to prevent the raising of the ribs, as is done in the Sylvester and Schultz methods. In the latter methods one force tends to counteract the other. This is avoided in the method here given.

Having enlarged the thoracic diameters to the fullest extent by raising the ribs, or rather, made it possible for them to be enlarged, we next proceed to force air directly into the lungs. When the ribs are raised the child's head extends sharply backward. This throws the cervical vertebræ forward and draws the larynx backward. Thus the flaccid œsophagus becomes compressed between the bones of the vertebræ on one side and the firm cartilaginous larynx on the other; as a consequence, the œsophagus is effectually closed and the air cannot be forced into the stomach, and must enter the lungs. This effectually disposes of the time-worn and false statement that mouth-to-mouth insufflation must force the air into the stomach instead of the lungs. This position of the head also draws the tongue and epiglottis forward far better than it can be done with the forceps, and there is no possible chance for the tongue to fall back and close the larynx. We now have an open passage-way through the mouth and larynx to the lungs, and there is no necessity of inserting the catheter.

The next step is to force air into the lungs. The arms still held up, the operator bends forward, and taking in a breath as he does so places his mouth over that of the child and blows the air directly into the lungs.

The air must and does enter the lungs and distend the collapsed air-cells, as can be determined by the fact that it can be heard leaving the lungs at the next step in this method. No great force need be used in doing this, although there is but little danger of injuring the air-cells, however great the force. It will be noticed that a safety escape is provided in this method for excess of air. The nose should be, and is, pervious, and any excess pours out through that aperture, thus relieving the pressure on the lungs. This completes the movement for introducing air into the lungs.

Expiration is brought about by doubling the child's body forward upon itself so as to crowd the abdominal organs against the diaphragm; at the same time the arms are lowered to the side, and the operator's left hand, still retaining the hands of the child, is brought against the front of the child's thorax, and then gently and steadily presses the ribs and sternum downward and backward. Thus every requisite is provided for forcing the air out of the lungs: the diaphragm is pushed up, the abdominal muscles are relaxed, the shoulders are lowered, and the thorax is compressed between the operator's hands, one on the child's back the other across the front of the thorax. After a dozen or fifteen complete movements, when a sufficient number of the collapsed air-cells have been distended one can hear the air rush out of the lungs when the pressure is made upon the thorax by the operator's hands. This completes the movement for expiration. Again the hands are carried upward and backward, the child's body is just raised off the bottom of the pail so that the weight of the body is on the arms alone, the head falls back, air is again blown into the lungs.

Now as to the philosophy of the method. It will be noticed that during the whole of the process much of the child's body is in the warm bath. This I conceive to be of great importance, and it is something that has not been applied, so far as known, in any other method.

The important thing in attempts at resuscitation in a bad case of asphyxia in the new born is to keep the child's heart acting. It is easy enough to supply air artificially to the lungs for the oxygenation of the blood, but unless

the heart sends the blood to the lungs, and then on through the tissues of the body, the oxygen put into the lungs is useless. Now, if the child's skin is allowed to get cold the blood in the capillaries ceases to move, and the effect is soon manifested on the feebly-beating heart. If the blood leaves the capillaries cooled it enters the veins at a low temperature and thus chills the heart itself. Again, the heart lies near the surface of the body, and in a half-hour may be directly chilled through the loss of heat from the surface of the body.

On the other hand, if the body is kept in a bath with a temperature of from 105° to 110° F., the capillaries are dilated, the blood can circulate freely, and heated blood may be carried to the heart. It is claimed by physiologists that when the circulation is active the whole mass of blood in the body passes through the capillaries of the skin in a few minutes. Now, if the body is in a warm bath the whole mass of blood has its temperature raised, and thus the muscles themselves soon become heated. Any one can demonstrate the fact on themselves by getting into a hot bath up to the neck. The thermometer in the mouth will soon show a rise of two to three degrees Fahrenheit. M. Morey's experiments proved conclusively that muscular tissue loses its contractility when its temperature is lowered, and regains it when the temperature of the muscles is raised up to a certain point. It has been ascertained that the maximum aptitude for contraction is exhibited by human muscles at about 40° C. = 104° F. This is about the temperature of the body of a healthy adult when immersed for some time in a bath at the temperature of 110 F.

The heart is a muscular organ, obeying all the laws of muscular action, and it seems evident that in an asphyxiated infant it will act with more force if the infant's body temperature is raised and kept at 102° to 103° F., than if it is lowered to 96° or 94° F., as it will be if the skin is exposed to the air for a short time.

Theory and practice both prove that the continued warm bath is a most important measure in the resuscitation of badly asphyxiated infants. The importance of having the child in a sitting posture during the respiratory movements has already been commented on.

In comparing the method here given with the best three methods heretofore used, namely, Sylvester's, Schultz's, and the catheter in the larynx, it will be seen that this combines all the advantages of the three usual methods without any of their drawbacks. For instance, in the new method, we have direct insufflation of air from the operator's lungs, as when the catheter is employed. We have exactly the same method of raising the ribs and sternum as in the Sylvester method, with the additional advantage of having the abdominal muscles relaxed. We have in the new method the descent of the diaphragm that is claimed as an advantage in the Schultz method. We have in expiration the same doubling of the child's body forward and pushing up of the diaphragm as are found in the Schultz and Schroeder methods. We avoid shock and exposure that are so often fatal in the Schultz method, and, at the same time, keep up the vital or animal heat in the infant during, perhaps, a long operation.

In recapitulation it may be said that the steps in the new method of artificial respiration in bad cases of asphyxia in the new-born are as follows:

1. Lay the child on its face for an instant with the head and thorax lower than the pelvis, and make quick but not violent pressure on the child's back. This is done to expel any fluids that may have been drawn into the child's mouth while passing through the pelvic canal.

2. Place the child in the sitting posture in a pail or tub containing six to eight inches of water as hot as can be borne comfortably by the operator's hand. The child is supported in this position by one of the operator's hands across the child's back, the child's head bent back and resting in the crotch between the thumb and forefinger of this hand. The child's hands with the palms to the front are held in the other hand of the operator.

3. The child's hands are carried upward until the child is suspended by the arms, the buttocks just raised from the bottom of the pail. The child's head now falls back, and the operator leans forward, and, mouth to mouth, blows into the child's lungs.

4. The child's arms are then lowered until the hand of the operator holding them rests across the front of the child's thorax. Then the body of the child is doubled forward, and, at the same time, its thorax is compressed between the operator's hands, one in front the other behind. This expels the air from the lungs and completes the movements.

Case I.—In March, 1890, I was called by an Italian midwife to assist her in the delivery of a child. The mother I found to be a stout, healthy primipara, aged twenty-one. The waters had come away forty-eight hours before I was summoned and there had been labor pains ever since, but no progress had been made. On examination I found the os only one-fourth dilated, the lips thick and firm, the pelvic roof but little retracted, and the vaginal canal wholly unfitted for the passage of a fœtal head.

I decided to wait a few hours; the patient meantime to receive hot rectal douches. Six hours later I was called again. Little if any change, except that the soft parts were more relaxed. The position of the head was face anterior.

Taking into consideration the conditions of the case, *i.e.*, the position of the head, the early discharge of the waters, the leathery condition of the soft parts, the large size of the child's head, and the fact that the mother was a fat, plethoric young woman, I felt sure that I had a tiresome task before me. Needless to say that I was not disappointed. The forceps were applied, and it took three hours of almost continuous traction of the strongest kind to deliver the child. The child's head did not rotate, and in spite of every care during delivery, the mother was badly lacerated, down to, but not into, the rectum. The child was apparently dead, no pulsation of the cord, and not the slightest pulsation of the heart could be felt by the hand. The midwife attended to the delivery of the placenta, while I gave all my attention to the attempt to resuscitate the child. There was no pulsation of the heart that could be felt by placing my hand over the child's præcordial region; but on putting my ear to this region I could very distinctly hear the heart beating at the rate of about sixty beats per minute.

Let me say here that in my opinion the practitioner should never trust to his hand to determine whether or not the new-born child's heart beats. It is really startling to put one's ear to a child's chest where the hand can feel no pulsation, and then hear with such distinctness the dull thud, thud, of the child's heart. Dependence should always be placed upon the ear instead of the hand in determining whether or not an infant's heart has ceased to beat.

In attempting to resuscitate this child I employed for a minute or two the usual slapping with the hand, rubbing with brandy, dipping into hot and then into cold water, but all to no purpose. The case was beyond the effect of reflex irritation.

The method of artificial respiration mentioned above was then employed. That it caused air to enter and leave the lungs could be determined by the blue color leaving the child's lips. Still there was not a single voluntary or spasmodic effort at inspiration.

I have said that at the beginning of my efforts the heart was beating at the rate of sixty beats per minute. This gave me a little confidence that I might revive the child.

At the end of fifteen minutes I removed the child from the bath, put my ear to its chest and counted the heart beats by my watch. The pulsations were one hundred and twenty per minute, I slapped the child quite vigor-

ously, and it drew up its legs with a slow, convulsive movement. But it made no gasping efforts to draw in the air, a movement that usually cheers the physician in these cases. Meantime the water in the pail had been renewed by fresh hot water, I set the child in it, and with my hand laved the water upon the child's breast and neck. Under the influence of these hot douches the capillaries could be seen to fill with blood, as shown by the skin turning red, thus showing that the heart was doing its part. Still no respiratory efforts. I commenced artificial respiration again and continued for ten minutes more. At the end of that time, the midwife stated that she could not deliver the afterbirth, and that the woman was flooding. I was compelled to leave the child for a short interval. Laid it on the table and told the midwife to rub it while I attended to the mother.

I was detained five minutes and then returned to my little charge. I found on putting my ear to its chest that the heart was beating only thirty times per minute. I had little hopes of resuscitating it, but wished to see what the effect of artificial respiration might be, and so replaced the child in the hot water and renewed my efforts. At the end of three minutes I removed the child, and found the heart beating at the rate of ninety per minute. At the end of ten minutes more the heart was beating one hundred and ten times per minute.

It was now a little more than three quarters of an hour since the child was born, and in spite of the fact that the heart was beating quite normally, and that there had been two reflex drawings up of the legs, there had not been the faintest effort at an attempt toward spontaneous respiration. It seemed to me that the nerve-centres governing the respiratory function or the nerve connection between these centres and the lungs had been injured, and the lungs could not voluntarily act. Artificial respiration, as I practised it, seemed to answer to supply the blood with air, and thus favor the heart's natural action. I resumed my efforts and continued them for fifteen minutes, making an hour since the child's birth. Heart beating over a hundred per minute, and skin and lips a good color. I suspended operations for three minutes; heart ran down to thirty beats per minute. Resumed my efforts, and heart was soon beating at ninety per minute. I had given up any hopes of establishing natural respiration, but was simply carrying on an experiment. An hour and fifteen minutes after the birth of the child, I suspended work for five minutes owing to my own fatigue. On resuming, the heart was beating very slow, less than twenty per minute, the child, however, made another spasmodic movement of its legs.

My efforts soon ran the heart-beats up to sixty per minute, and there it remained as long as I continued artificial respiration. I had become very much fatigued by this time, and occasionally laid the child aside so as to rest myself. Every time I resumed artificial respiration, I could increase the rate of heart-pulsation.

An hour and three quarters after the birth of the child the heart was beating very slowly, not more than eight or ten beats per minute. My efforts ran the rate up to forty beats per minute. I then definitely abandoned the experiment, owing to my own fatigue, not because my subject was exhausted. The child never made a respiratory effort during all this time. It seemed that the action of the heart might have been continued for many hours in this case had artificial respiration been continued steadily. I noticed that the more rapid the artificial respiratory movements were made the more quickly the pulse rose.

Respiratory movements in a new-born child should be made forty or fifty times a minute instead of twenty times, as usually taught. An infant breathes naturally about forty times a minute, and this rate should be the rule in artificial respiratory movements.

There are certain conclusions that may be drawn from this case:

1. The method of artificial respiration advocated in this paper ventilates the lungs. This was shown by the fact that for an hour and three-quarters the blood received a fair supply of oxygen, as shown in the capillaries of the skin, without the child making a single voluntary or spasmodic effort at inspiration.

2. It was demonstrated that the action of the heart is stimulated and continued by supplying the lungs with air. The pulse-rate rose and fell in direct ratio with the attempts at artificial respiration.

"Flint's Physiology" states that, in experiments on animals, "if the heart be exposed in a living animal and artificial respiration kept up, although the pulsations are diminished in frequency and increased in force, after a time they become perfectly regular and so continue just as long as air is adequately supplied to the lungs."

3. That in certain cases the respiratory function cannot be established, owing possibly to injuries to the medulla.

Case II.—Stout German woman. Multipara. I was called to the case and reached the house, according to the mother's statement, a half-hour after the child was born. From the circumstances of the case, I do not think this statement an exaggeration. The mother stated that when the child was born it screamed loudly for a minute, but she had neither heard nor felt it since.

The mother lay on a German feather-bed, resting on her elbow, in a semi reclining posture, thus making at the hips, in the soft bed an artificial pond that contained about a pail of mixed blood and amniotic fluid, lying in which, face downward, was the infant, apparently dead—drowned. It could not have been in that position less than a half hour, as the child was born just as the messenger left the house to summon me. I removed it and quickly rubbed it off with hot water. No pulsation of the heart could be felt and the child was limp and cool. On putting my ear to its chest I could just distinguish a faint thud at the rate of about twenty beats per minute. I put the child into hot water and commenced artificial respiration after the method given in the preceding case. In five minutes I listened to the heart-beat and found it much stronger and at the rate of about ninety beats per minute. No respiratory efforts yet. I resumed my work and in three minutes more (eight minutes from the beginning) the child made its first gasp. In a short time thereafter respiration was well established. The child is now living and healthy.

This was not a case of asphyxia neonatorum, strictly speaking, because the child cried immediately after birth and then was drowned

The case is introduced here because it illustrates two things: 1. The influence of artificial respiration on the heart; the pulse-rate running up from twenty beats per minute to at least ninety beats before the child made any respiratory efforts. 2. The ease with which a child is resuscitated after it has once cried and thus distended its air-cells, as compared with the difficulty of resuscitating a child, no more badly asphyxiated, but whose air-cells have never been distended and are completely collapsed, as at birth.

Case III.—Italian woman, primipara. Large male child, face anterior. A very tedious labor. Child born at length after delay with the shoulders. Badly asphyxiated. I commenced artificial respiration after the method described above. There were no reflex movements in this case. It was just three-quarters of an hour before the child gave the first convulsive, spasmodic gasp. Then ten minutes' unremitting effort before the second respiratory gasp was made. After this the respiratory efforts became gradually more frequent, but it was an hour and forty minutes before the function was established so that the child could breathe alone. Even then it breathed with difficulty, and it was more than twelve hours before the respirations were natural. The child made a good recovery.

Case IV.—Mother a young and fleshy primipara. An exceedingly tedious labor. Instrumental delivery after prolonged traction. The child was born with blue and

swollen face, and apparently badly asphyxiated. Before the cord was tied the child made a single convulsive effort at inspiration, and my hand could feel the heart pulsate. After tying the cord I asked the nurse to cut it. Unfortunately she cut it on the wrong side of the ligature, and, as a consequence, there was a quick escape of about three drachms of blood. The child immediately became blanched and relaxed, and made no further efforts at inspiration. I tried the usual methods of reflex irritation, expecting no difficulty in restoring respiration, but to no avail. I could now not feel the heart beat, and on listening at the chest could just hear that it was beating very faintly, and only about thirty times to the minute. It seemed to me then that the sudden abstraction of blood from the large umbilical vessels connecting so directly with the heart, had caused a shock that had nearly suspended cardiac action. It is an old and almost universally-accepted theory that, in the words of Cazeau: "When the child is born with a general injection of the capillaries of the head and trunk it is evident that the first indication is to relieve the engorgement of the head and lungs, which is done by promptly cutting the umbilical cord, and allowing a few spoonfuls of blood to escape."

It would seem that the theory on which such practice is based, however plausible it may seem, is unsound in fact. Even if there were any evidence to prove that there can be a dangerous congestion of the head and lungs during the labor, the active cause is over as soon as the child is born. Bleeding the child then is like locking the doors after the thief has left the premises. Such congestion, if present, would be best relieved by drawing the blood to the surface and by stimulating the heart, rather than by paralyzing it by abstracting blood from it. There are but eight ounces of blood in the new-born child and "a few spoonfuls" may represent a respectable proportion of the whole amount.

Without dwelling further on this point, it may be said, 1, that it has not been shown that a dangerous passive congestion of the brain and lungs often arises from a prolonged labor; 2, that, even if such a congestion existed, abstraction of blood from the large vessels leading to the heart after the birth is completed is a useless and dangerous procedure.

As a result of the umbilical bleeding in this case, what seemed a simple case of asphyxia was converted into the most obstinate one I have ever encountered. After fifteen minutes of artificial respiration, with the child in the hot bath, it gave a slight convulsive gasp. I removed it and listened to the heart and found it beating faintly at the rate of about sixty beats per minute. Even as I listened the heart rate grew less and the sound fainter, and a pallor spread over its surface. I replaced the child in the bath and recommenced treatment. The capillaries of the skin filled again, and after ten minutes there was another attempt at inspiration. These respiratory gasps becoming more frequent and at more regular intervals, after a half hour I removed the child and tried for a minute the Schultz "swinging method" of artificial respiration. An almost immediate collapse was the result; no more efforts at inspiration, and the lips became blue and the nose cold and white. Again artificial respiration in the hot bath, for thirty minutes continuously (making one hour up to this time), and the spasmodic gaspings were quite frequent, and it seemed as if respiration were on the point of being established. I removed the child and tried first the Sylvester method and then the catheter in the trachea. The gaspings ceased and very quickly the heart pulsations grew slower and fainter. Throughout the whole time during which artificial respiration was kept up in this case (a little more than two hours) the difficulty seemed to be in getting the natural circulation established. In this case, unlike Case I., the respiratory centres seemed ready to assume their function but were delayed by weakness in the circulatory centres. It took two hours or more of almost continuous efforts at artificial respiration before the function was established. Many times I stopped my efforts for a minute or two, or tried other methods, when the heart-rate invariably lessened rapidly, and the case went into a state of collapse.

When respiration was at last established it was slow and gasping for several hours. The next day the child had several convulsions, but these were overcome by the liberal use of bromide of potassium, and the child finally made a good recovery. At this writing the child is eighteen months of age, and mentally and physically bright and strong.

During the more than ten years in which I have practised the method of artificial respiration given above there have been many remarkable cases of recovery from asphyxia, but the above typical cases are sufficient to illustrate the principles of this method.

My conclusions are that in a bad case of asphyxia neonatorum, 1, Direct insufflation of the lungs is imperative; 2, this should be combined with movements to increase the diameters of the thoracic cavity; 3, that throughout the process the temperature of the child's body should be kept at or above 100° F., in order that the action of the heart may not be impeded.

These requisites can be met, so far as known to the writer, alone by the method of artificial respiration given above.

Minor conclusions are: 1. That artificial respiratory movements should be made at the rate of forty per minute instead of twenty, as usually taught. 2. That bleeding from the cord to relieve supposed dangerous congestion of brain and lungs is a useless and dangerous procedure. 3. That the physician should not depend upon palpitation, but upon auscultation, to determine whether or not the infant's heart beats. Many cases of asphyxia in the new-born are declared past recovery when if the ear were placed at the chest it would determine that the heart still beat and that the case was not hopeless. The old controversy whether or not a child can be resuscitated if its heart does not beat probably arose from a misconception—the viewing of the child from different sides. If the physician depends on his hand to determine whether or not the heart beats, as is the almost universal practice, then infants apparently without heart-pulsation may be revived very frequently. If, however, the ear detects no heart sound, then the case will, indeed, be past recovery. 4. That air in the lungs is an excellent heart-stimulant and together with external heat is a sufficient one.

39½ Washington Square, New York.

Dead Bacilli in Tuberculous Sputum.—The well-known Japanese bacteriologist, Kitasato, who works in the scientific department of Koch's Institute for Infectious Diseases, has made an important discovery, which he records in the *Zeitschrift für Hygiene*. He has discovered, by attempts at cultures from sputa, that the great majority of the tubercle bacilli found in sputum are dead, a fact which cannot be proved microscopically, because dead bacilli stain just as rapidly and as intensely as living ones, from which also they do not differ in form. The same is true of preparations made from the contents of vomicæ. This discovery is of considerable importance, from its bearing on the diagnostic value of preparations from sputum, and on the question of the transmissibility of pulmonary tuberculosis from one person to another. —*The Lancet.*

A Masonic Lodge of Scientists.—The *Revue de l'Hypnotisme* states that there is a Masonic lodge, in Paris, composed of students of philosophy and science, which has the suggestive and thoroughly Gallican title of the "Lodge of Scientific Materialism." Among its members are many physicians, professors of the School of Anthropology, members of the Academy of Medicine, and others.

INTESTINAL ANASTOMOSIS (WITHOUT RINGS) BETWEEN THE ILEUM, AND THE SIGMOID FLEXURE FOR INTESTINAL OBSTRUCTION (NEOPLASM) IN THE TRANSVERSE COLON.[1]

By ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL.

The patient shown this evening is a man aged thirty-eight who entered the New York Hospital, May 5, 1891, with a strangulated, left-sided inguinal hernia, for which, in my absence, he was operated on by my house surgeon, Dr. Albert Stanard. When the stenosis at the neck of the sac had been divided the strangulated omentum in the hernia was tied by silk ligatures in several masses and after its section the stump was pushed within the abdominal cavity. The hernial sac was also tied and divided at its neck, flush with the parietal peritoneum, and the distal portion removed. The inguinal canal, which had been exposed up to the internal ring by section of the aponeurosis of the external oblique muscle, was now narrowed throughout its whole length by the method known as Bassini's, the spermatic cord then replaced, next the divided fascia was sewn over it, and finally the skin. The radical operation supplemented the ordinary operation for a strangulated hernia. Everything went well thereafter—primary union occurred—and the patient left the hospital in four weeks. Two weeks after going home he began to have attacks of cramp in the hypogastrium, which lasted not longer than a minute at a time but were severe. He began also to be troubled with obstinate constipation. Shortly prior to his readmission to the Hospital, September 15, 1891, the physician in attendance detected a hernia in the left hypochondrium, running well into the epigastric region. He had never passed blood in his fæces or urine, though at times considerable mucous was noticed in his stools. He had lost flesh and strength since his cramps developed, though they would be relieved temporarily by a purgative. Examination revealed just above the umbilicus and extending inward from the left mammary line the outlines of a mass, dull on percussion, not movable with the respiratory action of the diaphragm, and separate from the spleen. By lumbar pressure the mass seemed either to be continuous with the kidney or possibly this latter organ itself was enlarged.

September 30th.—Dr. Stimson, then in charge of my wards during my absence abroad, made a five-inch incision along the outer border of the left rectus muscle, beginning one and a half inch below the free border of the ribs. The paricta peritoneum was found to be much thickened over an area of two to three inches in diameter, and to it was glued a portion of the large intestine. This adhesion was with some care and difficulty separated, and then it was seen that overlying and connected with the bowel was a thick mass of tissue with which the omentum and some loops of small intestine were conglomerated. This constituted a tumor of considerable size and beyond surgical interference. It was thought to be a cancerous neoplasm. Inasmuch as the signs of intestinal obstruction were beginning to show themselves, and from the nature of the lesion a stenosis of a serious character was not far distant, it was deemed advisable to make an incision through the abdominal wall, over the cæcum, and to fasten the latter in position, so that when it became necessary an artificial anus could be readily and safely established. The exploratory incision was closed by sutures, and recovery promptly took place without any untoward symptom.

I found the patient convalescing when I came on duty at the hospital, October 7, 1891. In the course of the following month he only had occasional attacks of colic and abdominal distention, which were relieved by a laxative. The provisional wound over the cæcum which, for two weeks, exposed the underlying bowel, gradually closed by cicatrization. From November 1st, the signs of obstruction, colics and constipation, became more decided, and it became necessary to interfere in his behalf. I deemed it wise to lay before him the advantages that I believed would accrue to him from an intestinal anastomosis, and also to point out, at the same time, that its creation was attended with more risk to life than the establishment of the artificial anus would bring. He was fully alive to the discomforts and the disgusting annoyances that would result from the opening in the cæcum. He determined to have the anastomosis made. This was done, November 14th, by a median incision, four inches long, running from the umbilicus downward. The sigmoid flexure was brought out through the wound, being normal, and only hampered by one or two slender but firm adhesions, which were evidently due to the hernial trouble. These being divided between two ligatures allowed the bowel to rest easily outside the abdominal incision. The cæcum was now felt for, and being recognized it was found that its adhesions to the old abdominal wound were so scanty that it was only held to the lower half of the cicatrix, so that if the attempt had been made to establish the artificial anus by simply plunging a knife through the cicatrix, escape of fæces from the opened bowel into the peritoneal cavity, would have been possible. With the cæcum as a starting-point, the ileum was reached, and a loop of it about eight or ten inches from the ileocolic valve was drawn outside the abdomen, and seen to be capable of being easily adjusted to the sigmoid flexure. These loops were laid on iodoform gauze, with which the rest of the wound was packed during the future operation. I did not endeavor at all to make an anastomosis nearer the seat of disease, not only because, surgically, one desires to get as far as possible from a neoplasm when it is a cause of obstruction and the cause is itself not to be excised, but also because the well-known case of Kocher—where a cæcal opening following a gangrenous hernia had thrown out of use the entire large intestine for over a year without any detriment to the patient's health—had shown that one could safely do the same in this case. Other similar clinical instances of shorter duration all leaned in this direction. A moment's thought also settled that the suggestion recently made of so operating at the time of making the anastomosis as to shut off any fecal current through the large bowel between the cæcum and the sigmoid flexure was unsound in principle as well as adding to the risk of the operation. This, it will be recalled, was proposed to be done by dividing the bowel above and below the neoplasm, invaginating the ends and closing the same by double rows of Lembert's sutures. The similarly sewn ends of the bowel not belonging to the diseased portion are in turn incised and a lateral anastomosis made. I only detail the procedure to express a condemnation of it. This form of lateral anastomosis, I consider, should always be preceded by a resection of the diseased parts, whether a neoplasm, stricture, or a gangrene of the intestine.

In the present case the anastomosis was easily effected by a four-inch incision in each bowel. Two or three bleeding-points required a ligature. The mucous membrane, after the opening in each bowel had been apposed, was sewn together at the ends of the incision, to prevent in this way, if possible, subsequent contraction of the orifice. The union was accomplished by two rows of continued Lembert fine silk sutures introduced with a milliner's round needle. To prevent mishap four or five interrupted sutures supplemented each row of the continued sutures. No rings were used to aid in this approximation of these openings. I have already called attention, in presenting, last spring, a specimen of gastro-enterostomy done with Abbé's rings (which is, I think, in one of the jars now on exhibition before you), to the tendency of the apposed intestinal incisions to slip out beyond the rings. This also occurs with Senn's plates, and in fact is common to all of these contrivances, so that special care in their use is demanded and often the escaping portion

[1] Presented at the meeting of the Surgical Section of the Academy of Medicine, January 11, 1892.

requires to be tucked in between the plates more than once before the restraining outside stitches are finally inserted. And in order to obviate the risk that comes from this, it has been felt by me (and I assume by others noticing the same peculiarity) that, instead of the few stitches advised by Senn to be placed outside the region of the plates, security would only come by a very perfect line of suturing, either continuous or interrupted, in this region. Moreover Senn has spoken of another danger that he himself has encountered. It is that the plate can be too tightly tied together and thus give rise to gangrene of the included intestinal or stomach walls. Animated mainly by these reasons, I abandoned in this case the use of approximation rings of any sort. The time occupied in the operation was about the same as when using the plates. This was about forty minutes. This is longer than if the plates were used without the carefully applied row of outer sutures. I may add in support of the non-use of approximative plates, that in Germany, where gastro-enterostomy has been and is yet most frequently done the old method is still resorted to, and that Czerny for repeated experience does the operation in this way in from twenty to thirty minutes.

After completion of the suturing the intestines were washed off with boiled water, and after the iodoform packing had been taken away from the wound they were replaced in the abdominal cavity and the parietal wound closed. The patient made an uneventful recovery. His bowels moved spontaneously on the fifth day. He was up and about at the end of three weeks. His stools were then normal. He was discharged from hospital December 18th, gaining then in flesh and weight. The tumor is felt yet through the abdominal wall above the umbilicus.

ULCERS OF THE LEG AND VARICOSE VEINS.

Their Treatment by a New and Simple Method, with Synopsis of One Hundred Cases.

By W. W. BREMNER, M.D.,

NEW YORK.

The object of this paper is to call attention to a very simple and successful method of treating ulcers of the leg and varicose veins. It has proved, after an extensive trial, very satisfactory in the relief and cure of that rather difficult class of cases.

This method was suggested by a paper of the late Professor Gamgee, of Birmingham, which appeared in the *Lancet*, several years ago, on "The Treatment of Recent Wounds of the Leg by Dry and Infrequent Dressings." In substance, it is an adaptation of his method to the treatment of ulcers. It is very simple and comparatively easy of application—in fact so simple, that any intelligent and competent person can use it, if the idea is correctly grasped. The advantage of practice is, however, very great, and in every town of any size, a medical man who would devote some little time and care to become proficient in its application, would obtain considerable practice and be the means of giving great relief to many a wretched sufferer. All the cases reported were treated in the city of Manchester, England, but during the last two years many cases have been treated in Canada and the United States, with even more satisfactory results.

In a short paper like this, it would be quite out of place to give any detailed description of the anatomy of the leg or of the circulation in it. It will be quite enough to notice that in the leg the arterial blood has the force of gravity to help it, and the returning or venous blood has this force to overcome. This is one of the great difficulties in treating diseases of the leg; the other is the injury to the general health ensuing from the enforced rest which is usually taken during their treatment. This injury is most marked in elderly persons inclined to stoutness. In health the disadvantage under which the venous circulation labors is counteracted by the strength of the coatings of the veins and the number of valves placed in them, which cause the contractions of the muscles surrounding the veins to force the blood upward. But when disease and pain occur more blood is carried to the limb by the arteries, and the muscles are used much less freely; the blood in this way overloads and distends the veins, so adding to the existing mischief. In course of time the veins become like India rubber tubing which has been over stretched and has lost almost all its elasticity.

The method by which the writer has succeeded in many cases in relieving this state of affairs, without requiring any rest in bed or cessation of work, is extremely simple, nevertheless he trusts that on this account alone it will not be rejected as unscientific. Its action is chiefly mechanical, and consists, in brief, of the application of a perfectly flexible, porous, and absorbent bandage in such a way as to restore the venous circulation to its normal state, absorb and disinfect all the discharges, and permit at the same time free and painless exercise. The change produced in the nutrition and healthy action of the leg is like that brought about by good drainage in an unwholesome swamp.

Cause of Ulcers.—The most common predisposing cause of chronic ulcers of the leg is a varicose condition of the veins, but whatever may have been the original cause of an ulcer, in the majority of cases, if not speedily cured, a varicose condition is produced. This fact does not receive the recognition it deserves in the larger works on surgery, but is emphasized very strongly by Dr. J. K. Spender, of Bath, in a little book published by him in 1868, in which also the principle of treatment herein recommended is adhered to, though the means adopted differ somewhat. Mr. W. H. Bennett, F.R.C.S. Eng., in some very interesting tables lately published by him in the *Lancet*, gives one hundred and seventy-four consecutive cases of varicose veins of the lower extremity under his care at St. George's Hospital. The percentage of chronic ulcers occurring among them was twenty-eight. Other diseases especially predisposing to ulceration are erysipelas of the leg, phlegmasia dolens or white leg, syphilis, and acute rheumatism. The reason why the first three should create a tendency to ulceration is apparent, but it is very remarkable that twelve out of the last fifty cases herein reported had suffered from acute rheumatism. The first fifty cases of the series were not questioned on this point. It will be conceded that there is no method of treatment known to the general profession which gives much satisfaction. Most of the great writers on surgery treat the subject in a very cursory manner. There are three essential indications to be fulfilled in order to treat an ulcer of the leg with success. First, to restore the circulation to its normal condition; second, to provide for the absorption and disinfection of the discharges; and third, to enable the patient to take free and painless exercise. The method here described fulfils these three indications almost perfectly.

The materials chiefly used are stockinette cotton bandages, three inches wide, in rolls of six yards each; Gamgee absorbent tissue, absorbent lint, oiled silk, or gutta-percha tissue, and ointments composed as below:

℞.	Vaseline	lb. j.
	Acid borac. pulv.	℥ j.
	Glycerine	℥ j.
M.		

℞.	Vaseline	lb. j.
	Acid carbolic	℥ iij.
	Glycerine	℥ j.
M.		

The boracic and carbolic ointments may be used interchangeably, and will be found very useful in the majority of cases. When the surface of the ulcer is gray, and it is sluggish in healing, carbolic lotion 1 in 80 on lint covered with gutta percha tissue will be found beneficial; and zinc ointment is suitable in eczematous cases, used alternately with the boracic ointment or acetic acid lotion, 1 in 80, on lint under tissue.

Subnitrate of bismuth, dusted on dry, is useful in many cases.

Application of the Bandage and Dressing.—To apply the dressing cut a piece of the Gamgee tissue a little larger than the wound or ulcer, spread over the tissue as thinly as possible some of the ointment thought suitable for the case. The tissue may be split in halves before use, but the gauze side should always be applied to the sore. When there is much discharge two or more thicknesses will be required. The tissue when spread should be laid on the wound, and the first bandage applied as follows: The patient, seated on a chair of ordinary height, should place his foot on a stand of the same height, or on a corner of the chair on which the operator sits, and wherever the wound may be situated the bandaging should be commenced at the foot. The first turn should be made over the centre of the ankle, going under the foot in a figure-of-eight; the second turn should go half an inch higher than the first, again going under the foot, and one turn round the front of the foot close to the root of the toes; the third turn should go half an inch below the first, then under and once round the foot again; the fourth, half an inch over the second, and the fifth, half an inch under the third, each turn going under and round the foot once only for each turn round the ankle, and coming just to the root of the toes. In cases where the ulcer is below the ankle, it is necessary in addition to make two or three turns directly under the heel, coming over the instep in front. The bandage must then be made to ascend the leg by spiral turns of about half an inch each, until the centre of the calf is reached; above the centre the turns should ascend from an inch to an inch and a half each. It is very important to attend to this point, as the bandage exerts all its force at the calf, and if too many turns are put on, the circulation beneath is obstructed. No reverses should be employed. In persons under one hundred and forty pounds weight two rolls of bandage are sufficient; when over one hundred and forty pounds and under one hundred and eighty pounds, three rolls will be required; and when over one hundred and eighty pounds, four rolls. There are six yards in each roll. When more than two rolls are used all but the last should be commenced at the foot; the last roll in every case should be applied from above downward in inverse order to the first. By attending to this, a stocking can be easily drawn over the bandages without disturbing the folds. For this purpose it is well to use a thin cotton or silk stocking, which should only be changed at the time of dressing, the ordinary stocking can be put on over it and removed at bedtime.

In applying the bandages the greatest care should be taken to regulate the pressure in such a way as not to cause stagnation of the venous circulation in the foot. This can be done by always applying rather more pressure to the foot than to the leg. The ideal is to have the pressure graduated in such a manner as to be greatest at the foot, and evenly and gradually less in ascending the leg. The arterial circulation should be almost unaffected, but the stasis in the veins completely overcome by the elastic pressure of the bandages. This is a purely mechanical matter, and is governed by the same laws which regulate the pressure of fluids elsewhere. A varicose leg is like an india-rubber tube, full of fluid, which from over-wear or over pressure has begun to stretch and bulge in places, and in such a tube the greatest amount of pressure would be at the lowest portion.

Changing the Dressings.—The dressings should be changed as seldom as possible; three times weekly is about the average number of times required in order to keep the pressure even and the discharges removed. When the discharge is very great it is necessary to change the bandages every day at the beginning of the treatment, lessening the frequency as the leg improves. Some legs hold the bandage in position much better than others. The attendant must use his own judgment. Some do well changed once or twice weekly, others require changing every day. A simple aid to uniformity in putting on the bandages is to mark a narrow strip of paper into half inches and lay it on the front of the leg as a guide. If these directions be carefully followed, it will be found easy to reduce almost any kind of swelling in the leg.

Bandaging after the Cure.—It is always better to continue the bandaging for at least six months after an ulcer is healed, and in aged persons for a still longer period. This may safely be left in the hands of patients themselves, after explaining clearly to them the method of application. In cases of varicose veins the bandaging must be continued for a still longer time. Two sets of bandages should be used, so as to permit of one set being washed when required. Care should be taken to direct the party who washes the bandages not to disturb the original folds, and in dressing to draw them out sidewise before rolling; on no account should they be stretched lengthwise.

While patients are under treatment they should not be allowed to remove the bandages themselves. When cured, they should be directed to remove them every night and reapply them every morning. As will be seen by the foregoing description, the three conditions of success spoken of above are almost perfectly fulfilled by this method. The stockinette is wonderfully elastic, and compresses the veins most completely and comfortably. The Gamgee tissue is absorbent to a very high degree, and in conjunction with one of the ointments described disinfects and absorbs all discharges, and the thinness and flexibility of the materials used permit of exercise being taken with perfect freedom.

Illustrative Case.—Mrs. T——, aged forty; housewife, with two children; general health good. Ulcer situated just above the inner ankle of the left leg, circular in shape, two inches in diameter, and deep and unhealthy in appearance. She had suffered from it for fifteen years. The leg was much swollen, and the pain "something dreadful." The veins were varicose. The ulcer had been caused by a knock accidentally received. She had twice been an out-patient at Manchester Infirmary, and had been treated by several private medical men. She came under treatment on May 1, 1884. Two rolls of bandage were used (twelve yards in all) and the ulcer dressed with carbolic ointment and Gamgee tissue as described. The dressing was changed every second day for a week, and afterward every third or fourth day. She experienced immediate relief from all pain as soon as the bandage was applied, and was discharged perfectly well on May 31, 1884. On making inquiry in April, 1889, she was still perfectly sound, and had never suffered any inconvenience in the interval. No rest of any kind was given, and she did her ordinary work during the treatment.

The medicinal treatment will not be spoken of. Every case must be treated on its own merits. Free exercise should be enjoined and wholesome and nourishing food recommended It is very important to keep the bowels regular, having a movement at least once each day. Is it safe to heal an ulcer of the leg? Yes, when free exercise is taken during the treatment. In every case treated by myself improvement in the general health took place.

In varicose veins the bandage should be applied as before directed, and will be found on the whole much superior to elastic stockings. In recent wounds of the leg the benefits of this method of dressing are seen to their greatest advantage.

In acute synovitis the equable and constant pressure obtainable in this way often seems to act as if by magic in reducing the swelling and inflammation.

A synopsis of the first hundred cases of ulcers treated was appended to this paper, but is omitted for lack of space. The average period of treatment was about five weeks. Eighty per cent. of the patients were permanently cured, in the remaining twenty per cent. the pain was relieved, and the swelling removed in almost every case.

SOME SUGGESTIONS IN THE MANAGEMENT OF LUNG FEVER.

By HENRY F. WALKER, M.D.,
NEW YORK.

The progress which has been made in the knowledge of pneumonia has been rather in its diagnosis and its pathology than in its treatment. Auscultation and percussion have revealed to us its early existence in many cases, but in many more, developing centrally, we are obliged, like our grandfathers in medicine, to make a diagnosis by chill, fever, pain, cough, and expectoration, while waiting for a central process to advance to the surface and to earshot. We have not made progress in its nomenclature.

Lung fever is a far better name for this croupous pneumonia than that which usually describes it. Pneumonia, or pneumonitis, ought to be limited to the catarrhal process, involving the deeper tissues, as well as the mucous surfaces of the bronchial tubes, while lung fever should describe the disease which consolidates the lobes, and which, with us, is often so prevalent as to be epidemic. In this pathological study has aided and confirmed clinical experience by proving, as in cholera, typhoid fever, and tuberculosis, the existence of the septic germ. The discovery of this bacillus has settled controversy in favor of those contestants who declared for an essential fever rather than an inflammatory process. If we consider it an essential fever our treatment and care of it will be in some measure changed.

The article, published some months since,[1] based on the treatment of the disease in the Massachusetts General Hospital, gives little commendation to the progress of our more recent therapeusis. In that, it is proven that the death-rate from the disease has been practically the same for many years. I do not, in this short paper, propose any method which shall be better for the relief of any individual case, and so diminish the mortality, but rather to diminish the number of cases and thus protect the community.

Every disease characterized by bacilli of animal origin is, by reason of its character, more or less communicable to others from the sufferer. I would rank lung fever high among the infectious fevers, and, therefore, hazardous to the attendants. The reason is obvious. The poison of lung fever, formed in the lungs, is likely to be found in the exhaled breath of the patients and in the contaminated air of the sick room.

I think no one with a large clinical experience would be willing to deny the possible infectiousness of lung fever. Almost every season of my own practice has demonstrated the probability, until I have been compelled to admit to myself its communicability. The death records in the newspapers cast their evidence on that side. Two weeks since a lady, ill with lung fever, whom I saw in consultation with a friend, was taken a corpse to a neighboring city; and ten days after her daughter, who had nursed her faithfully, succumbed to the same disease. A man whom I knew, a few miles away from here, died January 10th of lung fever, his wife January 18th.

These cases are incidents of the past four weeks, and serve merely as illustrations. The memory of every one of us can recall similar instances, too pronounced to be merely coincidences. If these be facts, and I think they are, they should lead us to treat our cases of lung fever so that the disease shall not spread from the individual to others. As great a measure of isolation is desirable as we should demand in typhus or scarlatina.

If we cannot cure the disease we may prevent its spread by recognizing its infectious nature, and thus, in a measure, stamp it out. It is not usually the trained and paid nurse who contracts the trouble. She is compelled to guard against exhaustion and takes needful rest and food. It is more likely to be the kind neighbor, who, perhaps, has never before "sat up" for a night, and to whom the loss of a single hour's accustomed sleep suggests exhaustion; or still more likely to be a father, mother, husband, wife, or daughter, who, with anxious cares, combines affectionate attentions and expressions of endearment not expected of a stranger or of a hired nurse. It is these who succumb to a poison inhaled.

I dislike the idea of another being added to the list of infectious diseases. The modern man is such a coward as regards disease or death, that to mention scarlatina or diphtheria disturbs a neighborhood. To put lung fever alongside the others would make him a greater brute than before—it would make one thing more to avoid and "pass by on the other side." If we expel every useless person from the room of the patient, and give caution to every one in needful attention upon the sufferer, we shall do something to limit the spread of our most fatal acute disease. It should be among the prime efforts of the physician, where illness prevails, to keep the well ones well.

While useless and curious people are to be excluded from the sick room those who remain are to be instructed as to the most perfect ventilation possible. Some disinfectant, like turpentine vaporized by boiling water, might do good—it is one which would be harmless and perhaps beneficial to the invalid. But the chief instruction to the attendant as to personal care is the avoidance of the breath of the patient. A little prudence in this direction would greatly aid. As I have before said, it is especially to relatives and intimate friends that such warning need to be given. A mother can scarcely be restrained from caressing a sick child, even though it be hazardous to herself.

To recapitulate: Pathology has shown that lung fever is likely to be an infectious disease. Clinical experience, I think, has proved it. If it be infectious it should be treated as far as possible by isolation, and attendants should be warned as to their personal care.

THE TREATMENT OF PULMONARY TUBERCULOSIS BY CREOSOTE.[1]

By GEORGE H. PENROSE, M.D.,
ASSISTANT SURGEON UNITED STATES SOLDIERS' HOME, WASHINGTON, D. C.

The subject of my remarks to-night is such a momentous one that I cannot attempt to deal with each different phase of the disease, but shall confine myself to the course and results of my experience in the use of creosote in the treatment of tuberculosis.

My attention was first called particularly to the use of creosote in such cases when Von Driver, in the *Berliner Klinische Wochenschrift*, No. 35, 1888, published the results of his cases under this treatment. Before this, however, there had appeared several articles upon the subject. To Bouchard and Gimbert is due the credit of bringing the use of creosote before the profession in cases of tuberculosis.

Beverley Robinson [2] may be said to be the pioneer of the use of this drug in America, as at this date he began using creosote internally, giving a dessert-spoonful of the United States Pharmacopœial preparation, which represents one minim to the ounce.

In 1885 Professor Robinson, in a clinical lecture at Bellevue Hospital,[3] strongly recommended the use of creosote by inhalations, giving the preference to equal parts of creosote and alcohol.

In 1888 Professor Austin Flint [4] published an article on "Creosote in the Treatment of Phthisis Pulmonalis." In the ten cases reported the drug was used by inhalation as well as by the stomach, the mixture used for inhalation consisting of equal parts of creosote, alcohol,

[1] Read before the District Medical Society of Washington, D.C.

[4] Ibid., December 8, 1888, p. 617.

and spirits of chloroform, of which ten to fifteen minims were placed on a sponge. The treatment was begun with inhalations of fifteen minutes' duration, three to four times daily, and increased until the inhalers were used almost constantly, except at night. This was continued from forty-six to ninety-one days. Dr. Flint's conclusions in these cases were, that in cases of solidification without cavities the effect was a prompt and decided improvement in all phthisical symptoms; in cases with large cavities the treatment seemed to have little more than a palliative influence.

Sommerbrodt, of Breslau,[1] in over five thousand cases, has proven that creosote is not merely a useful drug, but that it exerts a specific effect on the disease by the resistance it affords to the cultivation of tubercle bacilli. The author has given the drug in doses as high as twenty-five minims in the twenty-four hours

It has thus been shown that creosote has been used for a number of years, but you will notice that in every case the drug has been given in small doses, and each author has feared to push the medicine; or when pushed, it had caused so much nausea that it had been early discontinued.

Having a large number of cases of tuberculosis in the hospital with which I am connected, I have been enabled to study the use of creosote in upward of two hundred cases, and can safely say it is pre-eminently the most satisfactory medicament yet used to ameliorate the distressing symptoms of our tubercular patients. Our method of treatment is as follows: As soon as the patient is admitted he is thoroughly examined and a careful note made of each physical condition, his weight is taken, and a specimen of the sputum is collected the first thing in the morning; this is received into thoroughly cleansed porcelain capsules and sent to the bacteriological laboratory, where it is carefully examined microscopically.

Most of the cases of tuberculosis at the hospital of the United States Soldiers' Home are of the chronic varietv, and do not report until the latter stage of the disease has been reached. Many have been so low upon arriving as to be required to be transferred from the ambulance to the ward on a stretcher. As soon as the diagnosis of tuberculosis is made and confirmed by the microscope, the patient is placed upon pure beech-wood creosote, in the form of an emulsion of cod-liver oil and acacia, each drachm of the emulsion containing two minims of creosote; of this a tea-spoonful is administered three times a day for the first week, when it is increased to a tea-spoonful every three hours for another week. By this gradual process the system accustoms itself to the drug; should there, however, appear a tendency to nausea, the patient is directed to lie upon his back for half an hour after taking the medicine, when in every case this tendency has disappeared.

About this time we begin to notice an improvement; the harassing cough decreases, the appetite increases, the patients gain in weight, and the quantity of mucus expectorated is lessened. At this point the quantity of creosote is again increased to three minims to the drachm, and the dose given as before. By this gradual method the quantity of creosote has been increased to six minims eight to ten times a day, thus administering from forty-eight to sixty minims in the twenty-four hours. In almost every case where the drug has been administered as above, the results have surpassed my most sanguine expectations. The appetite returns, the weight increases by as much as from thirty-five to fifty pounds, the cough and expectoration decrease to the minimum, or cease entirely, the hectic flush disappears, temperature becomes normal, the night-sweats become a thing of the past, and the number of bacilli decrease greatly or disappear altogether, as has happened in several cases; the spirits rise with the gradual improvement, and a feeling of well-being exists.

As to the physical signs: The coarse mucous râles disappear, the breathing loses its bronchial character; cavities, which were plainly marked before, appear to be lessened in size, and all the signs too well known to be here mentioned show improvement. Yet, in a few cases that have gained in weight, ceased almost entirely to expectorate, and who pronounce themselves as feeling perfectly well, and whose sputum shows a decrease in the number of bacilli, show upon careful physical examination well-marked cavities still existing. Whether or not this be due to the fact that treatment has not been continued long enough, I am not at liberty to express an opinion, nor can I speak positively of the pathological changes which take place, as in but one case has a patient died who had taken the drug long enough to look for marked improvement. In this case, while the edges of the cavity showed unmistakable signs of healthy granulation and contraction, there was not sufficient evidence to say that such changes were due to the drug alone. I hope later to be able to give an opinion based upon researches made in the post-mortem room and the laboratory which will clear these points.

Many authors upon this subject complain of the drug producing such severe nausea that it could not be administered; this, I think, is due to the fact that the drug was pushed too fast, or that an impure article had been used, for much of the creosote which is sold as such is simply a crude carbolic acid, and is injurious to the system; the only preparation I use is from the distillation of beech-wood tar prepared by Merck, of Germany, and I do not think too much stress can be laid upon the necessity of using a perfectly pure article. I have induced Mr. Z. D. Gilman, of this city, to procure the proper drug, and he is now prepared to furnish it. It is possible that the objection as to the nausea may be overcome by the use of guaiacol, obtained by the destructive distillation of guaiac resin or from beech-wood tar, as recommended by Professor Max Schüller.

Another objection is its odor, and many private patients refuse to take it on this account; but may it not be hoped that this objection may be overcome by combining it with some inert substance to disguise its odor without decreasing its efficacy? Even should this be accomplished, the odor exhaled by the lungs cannot be disguised.

Concerning its deleterious action on the kidneys, I can only say that I have never noticed any such action, although I have examined many patients' urine.

In cases of laryngeal complications we have been in the habit of using steam inhalations of creosote combined with glycerine, and have found it all that could be wished for.

I think the result of my cases will compare favorably with those of Professor Schüller,[1] although his were among surgical cases, while mine were all medical cases. In his article he has tabulated 100 cases treated with guaiacol, of which there were 70 cured, 16 improved, 10 passed from under observation, and 4 died. I do not consider that the time of treatment has been of sufficient length, nor that sufficient time has elapsed after the treatment was discontinued, to form tables which can be taken as representing the facts in these cases, and hence I have not attempted them.

But the use of creosote has been of such marked benefit in my hands that I think it my duty to place these results before the profession, and my experience has been such as to agree with Professor Sommerbrodt, that the drug must be given in comparatively large doses, such as I have suggested, and continued for a long period of time.

I do not attempt to say that one of my cases has been cured, but I do say that many are now living and earning a livelihood by manual labor, who would have died long since had it not been for the use of this drug. It should also be noticed that in almost every case in which I have used the drug, the disease has been in the latter part of the second or in the third stage, and that we could not

[1] New York Medical Journal, October 5, 1889, p. 373.

[1] MEDICAL RECORD, January 23, 1892.

look for the same improvement that we might in the earlier course of the disease.

I will not burden you with the histories of any of the cases, as none were marked failures or marked cures, but in each there was marked improvement, and it is because of this gradual improvement that I think we have the more encouragement for continuing the use of creosote in every case of tuberculosis.

In conclusion, I should like to urge the use of creosote in progressive doses, and think that if previous observers had used the drug in larger doses their results would have been better and more decided. I cannot agree with Professor Flint in the assertion that creosote has but little more than a palliative action in cases where cavities exist. In several instances we have noticed decided improvement in such cases.

I do not claim, nor do I think, that we have a specific in creosote, but from careful observation of several hundred cases of this dreadful disease, I do think we have a drug of infinite worth, and, as such, deserving of careful use and more careful study.

CARDIAC THROMBOSIS.

By JAMES KENNEDY, M.D.,

SAN ANTONIO, TEX.

I was called to see a patient, about twenty years of age, who, according to the history obtained, had been ailing for about ten days; prior to this time she had been enjoying perfect health.

The physician in whose charge she had been from the commencement of her illness stated that she had complained of a headache which was very severe, but no other symptom could be elicited. Not being able to make a diagnosis his treatment had been directed toward the relief of this symptom.

When I saw the patient she was delirious, and had been so for some hours. The delirium had been of an active type, but now the patient was bordering on coma. The pupils were dilated, the skin was cold, and the pulse feeble and indistinct. Breathing appeared natural, although I neglected to auscultate the chest. A grumous material was vomited at the time I saw her. She passed into coma and died a few hours afterward.

I held a post-mortem examination upon the body of the deceased in order to ascertain the cause of death, and as all of the symptoms pointed toward the brain as being the probable site of injury or disease, that organ was carefully examined. It was very pale and bloodless, but no embolus or other lesion could be discovered to account for the anæmic condition.

The cerebral anæmia that existed served to explain the headache, dilatation of the pupils, the delirium, and coma that marked the close of life, but did not suffice to explain the cause of death in the absence of any other lesion. The thorax was opened and the contained viscera examined. This examination revealed the presence of a gelatinous clot filling the ascending and transverse aorta. The thrombus was of a yellow color, and slipped out of the vessel as soon as it was severed from the heart.

The discovery of the existence of this body was quite sufficient to explain the anæmic condition of the brain that evidently existed during the illness of the deceased.

On examining the heart a clot was found in either ventricular cavity very similar to the one already described, but paler in color, firmer in consistency, and more elastic. Each one was adherent by its base to the columnæ carneæ and musculi papillares, and fibrillar prolongations extended to and were lashed around the chordæ tendineæ. There was no discoverable lesion of the heart itself, the vessels, or any other viscus.

There can be no reasonable doubt that these thrombi were formed during the lifetime of the individual,[1] and that the gelatinous portion, which must have been of more recent formation than those found in the ventricles, became detached from the one found in the left ventricular cavity, and during systolic contraction escaped through the aortic orifice and was carried by the blood-stream into the aorta, where it was arrested, probably because of the resistance offered by the aortic curve being greater than the propulsive force behind it, and produced the symptoms which eventuated in death, not by entirely occluding the great blood-main, but by causing an amount of obstruction incompatible with the perfect nutrition of important centres so necessary to the perpetuation of life; and thus by a process of starvation causing a certain and complete failure of those centres.

The symptoms and manner of death seemed to warrant the above inference. If complete occlusion of either the ascending or transverse portion of the arch of the aorta had suddenly taken place death would have occurred much earlier.

Cardiac thrombosis being caused by coagulation of the blood within the heart, a few words relative to the conditions which favor this process are deemed necessary for the better elucidation of our subject. These are, briefly:

1. Obstruction to the flow of blood through the heart. Under this head we include stenosis of any of the orifices of the heart or blood-vessels, valvular insufficiency or diminution in the contractile power of the heart-muscle, whether due to degenerative changes or defective innervation (this latter, of course, is not really an obstruction, but is a cause of slow circulation through the heart, and in this respect acts as a favorable condition to the formation of a coagulum).

2. Changes in the composition of the blood. Whenever the fibrin factors are increased there is an exaggerated tendency toward coagulation. In the physiological condition known as pregnancy, as well as in the pathological conditions known as Bright's disease, phthisis, fibrinous pneumonia, and rheumatism, the tendency of the blood to coagulate is markedly increased.

3. Inflammatory changes in the heart itself—such, for instance, as endocarditis, particularly the ulcerative variety, wherein a roughening of the valves occurs which favors the deposition of fibrin.

However, it is well known that while these conditions favor coagulation of blood within the heart, they are, after all, only predisposing factors in the production of cardiac thrombi, for it has been found that any one of these conditions may exist and yet no thrombus be formed. Hence the problem of the etiology of cardiac thrombosis remains but half-solved until the determining cause be discovered. Since none of the conditions enumerated as favoring the production of "heart-clot" were found, either by post mortem examination or in the history of the case, this fact constitutes the essentially interesting feature of our paper, and suggests that there may be other conditions which are not distinctly pathological and have no symptomatology to characterize their existence, but which are yet capable of producing such changes in the composition of the blood as to favor its coagulation—cases, for instance, in which there is a deviation from the normal standard of nutrition and in which there is no organic visceral lesion.

That there is a great difference in the activity of the nutritive processes within the limits of health no one will deny, and that the composition of the blood will vary according to the activity of those organs concerned in its production is, I believe, an established physiological fact. It is possible that the condition known (vaguely) as fibrinosis may have an existence separate from those causes to which it is usually attributed, dependent entirely upon the relative activity of the various blood making functions.

[1] The color and consistency of the thrombi are sufficient to establish their ante-mortem character.

Diet for the Bald-headed.—Sufferers from premature baldness are now recommended to live on a diet of brown bread and oatmeal, which is said to possess remarkable virtue in promoting the growth of hair.

Clinical Department.

PYOSALPINX FOLLOWING MISCARRIAGE SUCCESSFULLY REMOVED.

By JOHN R. HINKSON, M.D.,

BLISSVILLE, LONG ISLAND CITY, N. Y.

Mrs. E——, aged nineteen, resident of New York City, was seen by the writer on July 3, 1891. She had miscarried at the fourth month, nine days previously, and was now suffering from intense pain in the left iliac region which became at times paroxysmal; her temperature was 102° F., and her pulse 120; she also had a purulent discharge from the uterus.

Believing it to be a case of incomplete abortion, a laminaria tent was inserted in the cervix, and the uterus curetted on the next day, when some pus and *débris* of membrane swere removed. It was noticed that the curette passed to a greater depth on the left than on the right side. After this operation the temperature and pulse fell to normal, the pain in the left side was also much diminished, only an occasional paroxysm occurring, but the discharge from the uterus continued. The patient remained in the state already described for about nine days, when the pain and fever returned with all their former intensity, and her condition became even worse than when she was first seen.

It was thought that the curetting might have been imperfectly done, and fourteen days subsequent to the foregoing operation, the uterus was again curetted, the cervix having been previously dilated with a laminaria tent. Some pus and pieces of membrane, having no resemblance to fœtal structures, were removed, and tincture of iodine was applied to the interior of the uterus. The temperature again fell to normal and the pain was greatly lessened. This condition lasted about three days, when the patient relapsed to her former state and a tumor was discovered in the left iliac region, parallel to Poupart's ligament. The tumor was sausage-shaped, being constricted at intervals; it was plainly felt on deep pressure through the abdominal wall, but could not be reached by vaginal examination. A pyosalpinx was diagnosed, and, on July 29th, laparotomy was performed at the patient's residence, which was a crowded tenement in New York City.

Having etherized the patient, an incision two inches long was made in the median line of the abdomen, and on cutting through the peritoneum a considerable quantity of clear serum escaped. On exploration the tumor was found to be the left Fallopian tube, much distended, and intimately adherent to the intestines and omentum. The incision was enlarged to four inches, and some of the intestines allowed to escape, it being found impossible to separate the adhesions with all of the intestines in the abdominal cavity. This having been done, the pedicle, which was four inches broad, was clamped with two of Wells's pedicle forceps and ligatured in sections, the tumor being finally separated with the actual cautery. The abdominal cavity was irrigated with Thiersch's solution, drained with iodoform gauze, and the wound closed by interrupted sutures of wire inserted half an inch apart. The dressing was composed of iodoform and mercuric and chloride gauze, over which was applied a layer of absorbent cotton.

The patient vomited incessantly for three days after the operation, her temperature ranged from 99° to 100.6° F., and her pulse from 100 to 120; she had also considerable pain, and morphine was administered hypodermatically in doses of half to three-quarters of a grain every three hours. On the second and third days nutrient enemata containing eggs, milk, and brandy were given every five hours.

August 2d.—The vomiting ceased, the temperature and pulse became normal, and the patient was allowed her customary diet.

August 3d.—Dressing changed; gauze employed for drainage removed; wound irrigated with hydrogen peroxide; no suppuration, nor any offensive odor; temperature and pulse normal; diet as before.

August 4th.—Temperature and pulse normal, bowels moved by enema.

August 7th.—Dressing changed; sutures removed; irrigation with hydrogen peroxide; temperature and pulse normal; slight diarrhœa.

After this date the dressing was changed every four days; the diarrhœa, which was probably due to the bad hygienic surroundings, continued for a week. The wound was found to be completely healed on September 25th, the patient having left her bed on the twentieth day subsequent to the last operation.

HIGH TEMPERATURE IN AN HYSTERICAL PATIENT.

By C. M. ALEXANDER, M.D.,

COLEMAN, TEX.

I was called to see Miss E——, about twenty-two years of age on July 13, 1891; found her suffering with dysmenorrhœa, and to all appearances she was having hysterical convulsions. With the aid of ordinary remedies she was up and about in five or six days.

I saw her again in October, and she was suffering in the same way. After this she went to the country, eight miles distant, and commenced to teach school. In February Dr. L—— saw her, at which time, to all appearances, she seemed as though there was no serious trouble. On taking the temperature it was found to be 110° F., and [illegible] afternoon. I was

broke.

Curious Case of Lead-poisoning.—The sanitary authorities at Leith are engaged in an interesting investigation as to the cause of a wholesale poisoning of a ship's crew by lead. It appears that as far back as 1890 a bark left Leith for New York and Melbourne, having been provisioned by a Dundee merchant, who had purchased the sugar for the crew in Amsterdam. Shortly after starting the crew began to fall sick, and, one by one, were reduced to such a condition that it was with the greatest difficulty that the ship could be worked. One of them died. It was then found that they had all been poisoned by lead, and, the provisions being examined, it was found that the sugar was to blame. No one yet knows how it came to be contaminated by the lead.—*Medical Press.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street

New York, April 9, 1892.

THE BURDENS OF MEDICAL LIFE AND A REMEDY.

A CURIOUS paper called the *Twentieth Century*, which treats in an amusing way the social problems of present and future centuries, quotes, with comments, a paper on "Ideality in Medical Science," by Dr. M. J. Burstein. This paper was originally published in *The Doctor's Weekly*. Its author describes in a vivid manner the exacting demands made by the public on the physician of to-day:

The result is, we are told, that some physicians are not strictly honest in their dealings with their patients They do not always seek counsel when it is needed, for fear of losing standing with the friends or losing the case altogether. They do not always report contagious diseases for fear of offending the family or injuring the patient's business.

Dr. Burstein's remedy is this: "Let the doctors of each and every State form an 'Order,' with a grand medical board (or call it State Medical Board, if you like). This board should have its subordinate or county societies; which, again, should subdivide into districts. Each district should have a certain number of physicians, according to the density of the population. A physician should have a certain number of patients under his care, or he may be appointed by the Grand Medical Board to a fixed number of families living in his district. Physicians may be subdivided into three classes, according to their standing in the profession: regular, attending, visiting, and consulting. These would be paid by the State in accordance with their standing and service, the average salary suggested being $3,500 a year.

The *Twentieth Century* does not think that this would be a good plan. We are inclined to think that the nineteenth century will agree in this case with the twentieth.

We believe, also, that the ingenious Doctor rather exaggerates the pains and difficulties of medical practice. At any rate, they do not deter an unnecessarily large number of estimable gentlemen from entering it. No physician, who takes any interest in his profession, finds it a task to take and read the medical journals, particularly the MEDICAL RECORD, or to study up his cases, or to see operations, to attend to his office hours, to dress himself well, and mingle with his fellow creatures. This is the fun of it. Of course bad bills, ungrateful patients, dangerous cases, large and expensive families, make life somewhat of a trial; but we fancy that there are burdens to be met in every kind of work. And no Grand Medical Order could do away with those of the physician.

CURING INEBRIETY BY STATUTE.

CIVILIZATION is advancing with a whoop in the happy, golden State of Iowa. Having tried to prohibit the use of alcohol, with some lack of success, it proposes to take up the other end and cure by State enactment all its victims. If the good citizens cannot kill the roots they will pluck the fruit and extract its poison. A bill has been introduced into the State Legislature to create County Boards of Dipsomania. They will have the power to see that all inebriates are treated and cured of their unfortunate infirmity. They are to be taken and placed in certain institutions where the county or the patient, as the case may be, shall pay $25 a week till the thirst for strong drink has passed away.

MEDICINE AT THE WORLD'S FAIR

SOME of the States are taking steps to have the medical and sanitary advantages of their respective localities represented at the World's Fair.

Dr. W. H. Baldinger, of Galveston, has issued a card to the doctors of Texas, requesting them to send him minerals, shells, or other products, representative of their counties, from which he proposes to construct a "Statuette of Hygeia," to be exhibited at the World's Fair in 1893, and at the Texas Exhibit at Galveston in 1892.

The State Medical Society of California has passed resolutions recommending that a papier-mache map of the State be prepared, showing the various forests, rivers, and sanitary resorts; also that $500 be awarded to the best essay on the climate of California. The *Pacific Medical Journal* adds sarcastically: "Many of our institutions would no doubt be exceedingly interesting to archæologists; and models of our dusty and ill paved streets, of our Receiving Hospital, Pest-house, and jail, and of the ruins of the New City Hall should be given a

prominent position in the antiquarian exposition building."

We await the action of the profession of this State in the matter of representation at Chicago.

It is doubtful if we could compete with the Cook County Hospital of that city and the serene and scientific atmosphere which surrounds it and its indicted Aldermen. But we might send a section of our $2,000,000 clean streets, and give them a representation of a coroner's jury trying a railroad case, or endeavoring to make political capital out of an ambulance surgeon. The workings of our hospital and dispensary system, by which we succeed in treating 100,000 well-to-do people for nothing, annually, might also prove of interest.

New York ought certainly to do something. It is a resourceful State, with a population of five or six millions, according to one's politics.

THE PROPHYLAXIS OF GONORRHŒA.

A WRITER in *The Therapeutic Gazette* has been studying with an enthusiasm worthy of a good cause the subject of the prophylaxis of gonorrhœa. His conclusions are indicated in the following paragraph which also gives a hint as to the somewhat erythritic condition of young Philadelphia:

"Undoubtedly," Dr. Martin says, "the best method of accomplishing prophylaxis is by forced urination. Before coitus the bladder should be moderately full, and immediately after the act is accomplished urination should follow, the stream being interrupted from time to time by pressing a finger against the meatus, so that the urethra may be widely dilated, and the acid urine may gain access to its crypts and follicles. Frequently a single emission is not followed by subsidence of erection, the penis not becoming sufficiently flaccid to allow of urination until two or three orgasms have been experienced. Of course, under such circumstances, the risk of contracting gonorrhœa is greatly increased; but it is probable that even in these cases the disease can be avoided in the very great majority of instances by prompt urination in the manner already described."

There is one way of preventing gonorrhœa which does not seem to have occurred to the virgin mind of the writer of the above. It is embodied in the seventh commandment.

CARING FOR INFANTS IN FRANCE.

FRENCH statesmen, despairing of obtaining any increase in the birth-rate in their land, are now turning their attention to the saving of the few children that are born, and some very stringent laws have recently been enacted. It is now forbidden, under severe penalties, for any one to give to infants under one year any form of solid food unless such be ordered by a written prescription signed by a legally qualified medical man. Nurses are also forbidden to use in the rearing of infants confided to their care, at any time or under any pretext whatsoever, any nursing-bottle provided with a rubber tube. A few weeks ago Dr. Ledé, Secretary of the Superior Committee for the Protection of Infants, was commissioned by the French Minister of the Interior to investigate and report on the various measures whereby the conditions of transport of sucklings sent from Paris into the provinces could be improved.

Efforts are also being made to break up the system of baby-farming, and to induce French, or rather Parisian, mothers to nurse their own infants.

Much of this action by the authorities has been at the instance of members of the Society for the Protection of Children, a comparatively recent organization, whose object is definitely expressed in its name. The president of this society is Dr. Rochard, who has preached the gospel of caring for infants for many years. He was one of the first to sound the alarm at the decreasing population of France, but for a long time his voice was like that of one crying in a wilderness. Only eight years ago, when in a public discourse he predicted that the population of France would be stationary before the end of the century, he was laughed at, and the press called him an alarmist. But his vindication as a true prophet has come even sooner than he anticipated.

At a recent meeting of this society, which was founded mainly by his exertions and in consequence of his note of warning, Dr. Rochard stated that France loses every year 250,000 infants, and that out of this number there are at least 100,000 whose lives could be saved with intelligent care. These lives were the more precious in the present period, for France could no longer afford to lose them, since in a single year the deaths outnumbered the births by nearly forty thousand. It was not easy, he said, to add to the births, but it was possible to diminish the death-rate among infants. If the 100,000 preventable deaths among infants were prevented, or if even one-half of the number of lives now needlessly sacrificed to ignorance or carelessness were saved, France would soon be repeopled.

But would not many of these saved children be weaklings, whose preservation would serve rather to lower the actual strength of the nation, although increasing the total number of its citizens?

MALPRACTICE INSURANCE.

THE directors of an accident insurance company of London advertise that they have made arrangements to insure druggists against claims arising out of errors in preparing medicines, or by or through any act or omission on the part of either assistants or principals, including legal charges for defending any actions that might have to be contested.

The next move will doubtless be to insure physicians against malpractice suits, or rather against the expense of defending them and against any possible damages. The idea seems a little odd at first, but it looks less so when it is considered for a while, and it certainly would be a boon to the physician unjustly accused of negligence, and would relieve him of the expense of such suits, although not of the odium, if he were adjudged guilty. However, if people knew that the physician was backed by a rich corporation which would not shrink from the trouble of contesting a suit, and which would place the best of legal talent at the service of the accused doctor, they would be less likely to bring a suit out of spite or in the hope of turning a dishonest penny, motives which lie at the bottom of a large proportion of malpractice suits.

We commend this move to the managers of our American accident companies, for we believe such a departure would be of mutual advantage to the insurer and the insured.

WHOLESALE GRAVEYARD INSURANCE.

The *Medical Press* of recent date comments upon a statement of a correspondent of one of the London dailies, bringing a very serious indictment against the medical profession, as well as against the insurance system in use among the lower classes. He says that in his district (Lancashire) a *good* doctor, for insurance purposes, is known to be a practitioner who will habitually give false certificates of death for insurance purposes, and a *bad* doctor is he who insists on telling the truth as to the cause of death. The smaller insurance companies, it appears, do business up to £25 on any life, without previous medical examination, and there being no evidence in these cases of the condition of health of the patient at the time of insurance, the moment a patient is declared to be incurable the relatives and friends proceed at once to get as much money on the life as they can. The patient, of course, soon dies, and it is alleged by the correspondent that the doctor is expected to facilitate the recovery of the policy amounts by certifying old-standing phthisis as bronchitis of three weeks' duration, cancer of three years' growth as a tumor of three weeks, and so forth. If he is troubled with a conscience and objects to certify to lies, he forfeits a valuable connection, and the local insurance agents "boycott" him because his preternatural truthfulness prevents them from doing what they consider to be legitimate business. It would be interesting to learn the ratio of "good" and "bad" doctors in Lancashire. Possibly, and this is to be hoped, the correspondent was simply generalizing on the knowledge of one or two specific instances, and thus, as certain o'erguid people are prone to do, libelling a whole class because of the sin of a few individuals.

FOREIGN PHYSICIANS IN FRANCE.

A society has just been established in Paris of foreign medical men practising in France. The number of these in Paris is said to be about two hundred and fifty, or one-tenth of the total number of doctors in that city, but most of them studied medicine in the country and so may, except for the accident of birth, be regarded as really French physicians. The *Bulletin Medical* says that about one hundred foreigners apply every year for authorization to practise medicine in France, but that not more than half this number enter for the required examination. A few each year receive an authorization to practise from the Minister of the Interior without passing any examination, but in this case the right to practise is usually restricted to certain districts, as at Nice or Cannes, and may also be revoked at any time by the Minister. The same journal remarks that although there have been some very successful foreign specialists in Paris, there have also been many failures, and it instances a number of these who have either given up the practice of medicine entirely, or have packed their trunks and betaken themselves to South America or elsewhere, in the hope of scoring a success at last.

A SUICIDE CLUB.

A cable dispatch from Bucharest reports that the Roumanian authorities are much stirred up over the discovery of a club formed among the cadets of the Roumanian Military School, at Krajova, the members of which were pledged to commit suicide as soon as their names should be drawn. The cadets belonged to the upper class in Roumania, and the members of this club were all the sons of prominent families.

The club is said to have originated in one of the cadets having read, some time ago, of the existence of such a club in America. He called the attention of his associates to the matter, and at first, in jest, they entered into a compact of a similar kind. The survivors have confessed that they were not really in earnest when they began, and were greatly shocked when the first whose name was drawn drew a pistol without a word of warning, and shot himself dead. The others then felt bound in honor to follow his example, whenever their names came out in the fatal lottery. Others were admitted to the club, until it numbered nineteen members. Five cadets in succession took their own lives this week, all in the same manner, by shooting with a revolver, and all without apparent notice. The authorities of the school became alarmed and instituted an investigation of the mystery, the result of which was the discovery of the Suicide Club. It is said that the surviving members of the club will be tried for murder in having deliberately aided and abetted unjustifiable suicide, and it is probable that the ringleaders at least may be convicted and shot according to military law.

The American story referred to, upon which this tragedy was built, was of course pure fiction. It was written by a newspaper man, who never intended and never dreamed that it would be taken in earnest by anybody. It is almost incredible that the mere fancy of an ingenious American writer should have resulted in an epidemic of self-destruction among the flower of the youth of far-off Roumania.

The Champion Tooth Extractor.—The champion tooth drawer of the world is said to be a monk, Fra Orsenico, of Rome, who operates by the Japanese method—that is, with the simple instruments provided for him by nature in the shape of his thumb and forefinger. His extractions average one hundred a day, but there are days (perhaps when an east wind is blowing) when the number does not fall far short of four hundred. The good brother seems to be as proud of these dental trophies as an Indian brave of his scalps. He has two boxes containing thousands of more or less dilapidated teeth from which he has delivered his patients; these are kept open in his operating-room, doubtless *pour encourager les autres*. There seems to be some doubt as to who has the honor of having extracted the largest number of teeth at one sitting. An American dentist, Dr. Thomas Sneel, is said to have relieved a gentleman of twenty-seven in five minutes, but a Plymouth doctor seems to have broken the record by extracting thirty-one at one fell swoop. He would, doubtless, have given an epic completeness to his work by drawing the thirty-second, but, unfortunately, nature had been beforehand with him.—*British Medical Journal*.

News of the Week.

A Bill to Prevent Dissection.—It appears that one Senator Smith has been introducing at Albany a bill prohibiting all disposition of human bodies except by burial. Knowing the material of which the present legislature is composed, nothing can surprise us, but this special Smith must be even more so, as it were, than the others. Go back to your ash cart, Senator Smith, to your saloon, your tonsorial palace or whatever you ran for a living before you went to Albany, and try not to mortify us. Perhaps the safest way will be for you to consult some educated adult before exposing yourself again.

A Curious Patient.—As good an instance of surgical wit as can be found is still told about the staff of one of this city's hospitals. A dangerous operation was being performed upon a woman. Old Dr. A——, a quaint German, full of kindly wit and professional enthusiasm, had several younger doctors with him. One of them was administering the ether. He became so interested in the old doctor's work that he withdrew the cone from the patient's nostrils, and she half roused and rose to a sitting posture, looking with wild eyed amazement over the surroundings. It was a critical period, and Dr. A—— did not want to be interrupted. "Lay down dere, voman," he commanded, gruffly. "You haf more curiosity as a medical student." She lay down, and the operation went on.

Death of a Specialist in Duello Surgery.—Dr. F. Immisch, of Heidelberg, recently died. He achieved great fame as specialist in the surgery of the duello among successive generations of the combative youth of Heidelberg, having, during forty years of practice, officiated at more than thirty thousand "affairs of honor;" the remains of Dr. Immisch, who was seventy-two years of age, were, in accordance with his own request, burnt in the new crematorium at Heidelberg.

Paracresotic Acid, a New Antipyretic.—Egasse draws attention to the value of paracresotic acid as an antipyretic. It has been employed in the form of a cresotate of soda by Loesch, who found that doses of 6 to 8 grammes were perfectly well borne by adults. Demme has chiefly employed the drug in children for its antipyretic and antifermentative action. He finds it of great benefit in acute articular rheumatism, having somewhat the same action as salicylic acid, while it is better borne. In the catarrhal pneumonia of children it has been employed in the dose of 10 centigr. every two hours, and has shortened the course of the disease and rendered recurrences less frequent. In typhoid fever it diminished the diarrhœa. It also gave good results in the gastro-intestinal catarrh of nursing women. The maximum daily dose for young children should not exceed from 0.5 to 1 gramme, but young adults may take from 3 to 4 grammes daily.

The Pupils of M. Charcot celebrated his recent promotion to the rank of Commander in the Légion d'Honneur by a banquet. Thirty-five guests were present, the invitations being restricted to M. Charcot's former and present *internes* and *chefs de cliniques*. The toast of the evening was proposed by Professor Cornil. M. Charcot, in replying, said: "Je suis trop ému pour vous répondre; mon cher Cornil, laissez-moi vous embrasser." An *accolade* was in true French fashion bestowed after each speech. Finally M. Charcot rose and announced the successes of his pupils.

The New York Otological Society has recently been organized. The meetings are held upon the third Tuesday of November, January, March, and May. The work of organization was completed at a meeting held on March 22d, at the house of Dr. Gorham Bacon, at which time the following officers were elected: *President*, Dr. Albert H. Buck; *Vice-President*, Dr. Emil Gruening; *Secretary*, Dr. E. B. Dench. The first regular meeting will be held on Tuesday, May 17th, at 8 P.M.

Chicago Water and Chicago Fever.—The *N. A. Practitioner* says: "No one can deny that the water is bad. A student of the Institute of Technology of Boston spent most of last summer at the Post-Graduate Medical School, making bacteriological studies of the water in the pipes and in the lake. These studies furnished without doubt the basis of the Boston newspaper tirade on our water supply. The health department does not conduct any bacteriological studies. That they still resort to chemical examination of water shows that they have no conception of what should form the basis of study. Our Drainage Trustees are spending time and money without in any way meeting the needs either of the future or of the present. The newspapers howl, but nothing comes of it. The sewers still empty into the lake, and the barges still carry out their loads of garbage and offal and dump them beyond the breakwater. Two thousand patients died of typhoid in Chicago last year. This means that six times as many were sick with the disease. It is safe to say that each one of these was unproductive, if not an actual expense, during eight weeks."

The Brooklyn Dermatological and Genito-urinary Society has been organized, with Dr. Samuel Sherwell as President, Dr. A. E. Smylie as Vice-President, and Dr. George D. Holsten as Secretary and Treasurer. The meetings, which are private, are held on the first Friday of each month, except July, August, and September.

Arsenic in Household Utensils.—Massachusetts is becoming more lenient toward arsenic. A legislative commitment has recently reported unfavorably on a bill prohibiting the manufacture of household articles containing arsenic.

The Woman's Medical School at Johns Hopkins University.—The trustees of the medical department of Johns Hopkins University received last May, about $111,000 as a preliminary endowment obtained by the Woman's Fund Committee, for the purpose of securing for women medical instruction at the University. They also received a promise of $100,000 to be paid in February of this year, on condition that the sum necessary to make up the half-million dollars should be raised by that time. The time is now past, and the money has not been raised.

The Duodecimal System.—The Dosimeter system threatens to be superseded by the Duodecimal system. At the meeting of the Academy of Medicine of Paris, February 2, 1892, M. Polaillon read a paper by M. E.

Trouette on a new method of posology by duodecimal dosage of toxic remedies. This method should be applied to the alkaloids and all dangerous preparations. With this system of medication there would be no chance of error or accidental poisoning. It consists in dividing into 12 pharmaceutical doses (granules, pills, confections, wafers, capsules, pastilles, etc.) the maximum dose of a remedy that may be safely given to an adult within twenty-four hours. Each dose represents then the twelfth part of the maximum daily dose, so that, whatever the remedy, 12 doses may be ordered with safety in the twenty-four hours; as, for example, 1 cachet every two hours or 2 cachets every four hours, or, if the case be an urgent one, 12 cachets may be given at once. The number 12 represents the maximum dose for an adult; but it must not be forgotten that this dose varies according to age, sex, habits, tolerance, the stage of the illness, and many other circumstances that might be mentioned. M. Polaillon concludes that this method is an excellent one, and would be of great advantage if it were generally adopted.

College Commencements.—The Western Reserve Medical College graduated a class of thirty-four at its last commencement.

The War Against Quackery, in Louisville, is just now being vigorously pursued by the State Board of Health through its able secretary. Some notorious quacks have been forced to quit the field, and it is only a question of time when the city, as well as the State, will be purged of these getters of money under false pretences.

The Death of Dr. Meymott Tidy, the well-known author of the "Treatise on Legal Medicine," is announced.

Professor Crede, the distinguished gynæcologist and obstetrician, died at Leipzig on March 14th.

The Royal Medical Society, of Vienna, is to have a building of its own. The emperor donates 5,000 florins for this purpose.

A Columbian Medical Congress at Madrid.—A meeting of representatives of the medical profession throughout Spain was held at Madrid the other day, under the presidency of Dr. Aguinaga, to consider the expediency of organizing a Spanish-American Medical Congress, to be held at Madrid this year, during the celebration of the quadricentenary of the discovery of America by Columbus.

Ether Drinking.—The practice of ether drinking, which had become so common as to cause considerable alarm in Ireland, has begun to diminish as a result of very stringent laws. But it has been discovered lately that the habit is rapidly spreading in Russia, to such an extent indeed that the Government has found it necessary to prohibit the sale of ether, and of substances containing it, such as Hoffman's anodyne, except under severe restrictions. In Paris, also, ether drinking has become quite the fashion. It is taken there usually with cognac.

Found at Last is the place where a doctor is wanted—at least *was* wanted, for there are probably several there by this time. The place is North Gisborne, New Zealand. The residents of the place have guaranteed $1,000 per annum to any physician who will settle there, and the Government has promised to add another $1,000.

Busts and Pictures are Unsanitary, dyspeptic, and unsafe, according to Paris hospital authorities. M. Peyron, the Director of Public Assistance, lately received a portrait of Dr. Gallard and a bust of Dr. Roger; the former he proposed hanging in the gynecological ward of the Hôtel Dieu, and the latter in the Roger ward of the Children's Hospital, but the Conseil de Surveillance objected on sanitary grounds. Dr. Félizet, a pupil of Dr. Dolbeau, wished to place in the operation theatre a bust of his late teacher, but the Conseil de Surveillance again objected, and henceforth all busts, and portraits, and art objects whatsoever, given to hospitals, will be placed in the *Salle de Médecins*, where such rigorous antiseptic measures need not be observed as those enforced in wards and operation-rooms. If this particular wave of thought strikes New York, we tremble at the æsthetic loss which may result. The chromos, crosses, immortelles, and scriptural verses which adorn our hospital wards will have to go and the suffering patient will have to contemplate the unrelieved continuity of aseptic walls.

Notes on Italian Surgery.—Dr. Edward Haughton writes to the *British Medical Journal:* "In my brief stay at Naples and Genoa I have taken note of the sanitary state of these towns, and seen some operations in the Ospedale degli Incurabili at the former place and in the Pammatone at the latter. Italian surgeons frequently perform operations which are not often attempted in England, and use chloroform for a long time, apparently without fatal results. They do not use any mixture with ether or spirit, and only employ a small wire inhaler covered with flannel (masque d'Esmarch), which appears to answer best of all. Junker's appararus they reject entirely. Among other operations which I saw was complete excision of the great toe without any anæsthetic except only the compression of the limb, stopping the circulation by Esmarch's india-rubber bandage, fastened by hooking after a couple of turns round the limb. The patient appeared to feel nothing. No "Listerism," but only gauze impregnated with ten per cent. of iodoform used as subsequent dressing. Cocaine injections of four per cent. (amount one or two centigrammes of solution) were used in one case. One deep abscess of the neck was opened in the mastoid region behind the insertion of the sternocleido-mastoid, with immediate relief of breathing and of the pressure on the œsophagus. When empty the surgeon (Professor Ceci) was able to feel the internal carotid artery through the walls of the abscess; no anæsthetic was used in this case. I was informed that one of the surgeons in the hospital at Naples had excised a tumor (presumably lymphadenoma) necessitating removal of portions of one carotid artery, one jugular vein, and one vagus nerve, and that the patient lived about two months after this.

Ohio Doctors Insulted.—The Ohio Legislature has rejected the bill providing for regulating the practice of medicine in Ohio. We are told by the *Lancet-Clinic* that in rejecting it speeches and remarks insulting to the medical profession of Ohio were made. The *Lancet-Clinic* is most indignant and urges the physicians of Ohio to fight harder than ever for this bill. We trust our brethren will learn the golden rule of politics, talk little, and look out for a "pull."

Reviews and Notices of Books.

TREATISE ON GYNECOLOGY, MEDICAL AND SURGICAL. By S. POZZI, M.D., Professeur Agrégé à la Faculté de Médecine; Chirurgien de l'Hôpital Lourcine-Pascal, Paris; Honorary Fellow of the American Gynecological Society. Translated from the French edition under the supervision of, and with additions by, BROOKS H. WELLS, M.D., Lecturer on Gynecology at the New York Polyclinic; Fellow of the New York Obstetrical Society, and of the New York Academy of Medicine. Vol. I. Pp. xxii., 581. With 305 Wood Engravings and 6 Full-page Plates in Color. New York: William Wood & Co. 1891.

WE are glad to welcome an American edition of this admirable work, the appearance of which in French, a little over a year ago, elicited universal approval. The present volume is not merely a smooth and accurate translation, but is essentially a revision of the original work, with such modifications and additions as render it particularly adapted to the needs of English readers. Dr. Wells has accomplished his work so thoroughly that he can have the satisfaction of feeling that he has improved on the original, and that is saying a great deal. A comparison of the French and American editions shows how superior the illustrations, typography, in fact the *tout ensemble* of the latter are to the former. The editor has shown excellent judgment in the omission of useless cuts such as would only confuse the general reader, by reason of their unfamiliar appearance, and the substitution of others which are more intelligible. The six colored lithographs (two of which represent the gynecological operating-room of the Johns Hopkins Hospital) form an attractive addition. The colored cuts, representing section of the normal and diseased endometrium, have been beautifully reproduced (Figs. 90 to 93, 100, 105, and 111). References to literature have been placed at the end of each chapter instead of at the bottom of each page, as in the original, which is more convenient for reference. The translator's comments are enclosed in brackets. The most important, with which we are heartily in accord, is in regard to the value of trachelorrhaphy, an operation which (like all foreign writers) the author both judges and describes superficially, believing that "it has no advantages."

Although we have already reviewed at length the French edition, believing that the translation should be in the library of every intelligent practitioner, as well as gynecologist, we would briefly call attention again to certain unique features of the work, which render it *facile princeps* among treatises on diseases of women. In this progressive age what the reader first demands of a new book is that it shall be fully abreast of the times; next, that the writer display evidence not merely of exhaustive research and judicious compilation, but the power of condensing information within the smallest possible compass.

A clear, forcible style, intelligible cuts, which really illustrate the conditions described in the text—these are all important. It was at once evident, on the appearance of Pozzi's work, that the talented author had exactly hit the popular need for a work on gynecology which should leave the beaten track and represent the broad, cosmopolitan spirit of modern medicine. The instant and universal popularity of the book stamped it as the product of a master, even if it had not stood the test of exacting criticism. Everything about it is modern. One breathes a sigh of relief as he misses the ancient illustrations, the out-worn theories of a former generation. The surgeon recognizes the most approved instruments and technique, operations being described better than they were by those who devised them; the pathologist the results of the most recent investigations in his department. The descriptions of operations are so lucid and so admirably illustrated, that even the tyro can grasp the essential points, a rare commendation for a surgical work.

The present volume contains twenty-two chapters, the first four, which are introductory, dealing with the subjects of antisepsis, anæsthesia, sutures, and gynecological examination. Metritis (a term which the acute author recognizes as an unfortunate one, though, like a true Frenchman, he will not abandon it) includes three chapters; uterine fibroids, six; the surgical side of the latter is most prominent. Cancer of the uterus is discussed in three chapters, with full descriptions of the different operations, radical and palliative. Four chapters are devoted to displacements of the uterus, Chapter XVIII. being the most exhaustive review of the different methods of ventro-fixation that has yet appeared. The author's tendency being strongly surgical, the non-operative treatment of displacements receives less attention than usual. The sections on pessaries are supplemented by occasional judicious comments by the editor, which serve to render them more intelligible to American readers. A chapter on inversion and a closing chapter on the disorders of menstruation complete the volume. As we have before stated, the translation is a careful and scholarly one, faithfully preserving the terse, vigorous style of the original. Prolixity, the glaring fault of most French writers in every department of literature, is conspicuously absent—one of the principal reasons, in our opinion, why the author has been so much more successful than his *confrères* in winning for his book the careful consideration of busy workers. We cannot see how one who desires to be *au fait* with modern gynecological surgery can afford to be without Pozzi's treatise, since it is not only the most modern and exhaustive monograph on the subject, but it will be several years before it is displaced by a better one.

PRACTICAL MIDWIFERY. A Handbook of Treatment. By EDWARD REYNOLDS, M.D., Fellow of the American Gynecological Society, of the Obstetrical Society of Boston, etc.; Assistant in Obstetrics in Harvard University; Physician to Out patients of the Boston Lying-in Hospital, etc., etc. With one hundred and twenty-one Illustrations. Pp. xiv., 421. New York: William Wood & Co. 1892.

ALTHOUGH it must seem as if a manual of obstetrics must be mainly a compilation from larger works, such is by no means the case with this excellent little handbook, which really supplies a vacancy in the literature of the subject. In the modest preface the author states that his aim is to instruct students and inexperienced practitioners how to manage a case of labor under every possible condition, by furnishing all those minor details which are omitted in the larger text-books. He has been eminently successful, as every teacher of obstetrics will acknowledge on noting the careful and conscientious manner in which every point has been elaborated. Dr. Reynolds is not a mere compiler; every page of his book represents the result of personal experience at the bedside. It is divided into six parts (twenty-eight chapters), treating of pregnancy, normal labor, obstetric surgery, abnormal labor, the pathology of labor, and the puerperium. Under the head of pregnancy we note as especially good the sections on ectopic gestation and abortion. Chapter VI. contains unusually clear rules for diagnosing the presentation, and Chapter VIII., on normal labor, will be invaluable to the tyro, as well as the chapter on delayed labor which immediately follows it.

Of Part III., on obstetric surgery, we need only say that no previous writer has ever been more successful in condensing so much practical information within such a short space. Clearness is not sacrificed to conciseness, but every operation is described in detail, so as to be understood by one who has never seen it performed.

Chapter XV. contains the first satisfactory rules for the management of posterior positions that we have seen in an English work. The text-books used in our schools are

ntterly valueless in this respect, since they treat this important subject very superficially, entirely undervaluing its importance. Breech-presentations receive careful attention. Chapter XIX., on hemorrhages, the sections on lacerations of the parturient canal, and on the resuscitation of the new-born deserve especial commendation. Under Part VI., we note particularly the chapters on diseases of the breasts and on septicæmia. It is impossible to do justice to this admirable little book in a hasty review. It clearly contains the true elements of success—clearness, conciseness, and a constant recognition of the needs of the reader. We predict for it a favorable reception and wide spread popularity. The typography, binding, and illustrations are worthy of the well known publishers whose names appear on the title-page.

Physical Diagnosis: A Guide to Methods of Clinical Investigation. By G. A. Gibson, M.D., D.Sc., F.R.C.P. Edin., and William Russell, M.D., F.R.C.P. Edin. With 101 Illustrations. New York: D. Appleton & Co. 1891.

A concise and very practical work on the methods of diagnosis. It is admirably adapted for students and beginners in medicine. The illustrations are well executed and very profuse, considering the size of the book.

Diseases of the Skin. A Manual for Practitioners and Students. By W. Allan Jamieson, M.D., F.R.C.P.Ed., Extra Physician for Diseases of the Skin, Edinburgh Royal Infirmary; Consulting Physician, Edinburgh City Hospital; Lecturer on Diseases of the Skin, School of Medicine, Edinburgh. Third Edition, revised and enlarged, with Woodcut and Nine Colored Illustrations. Philadelphia: Lea Brothers & Co. 1892.

The first edition of this work appeared in 1888, and the following year a second. The present volume has been revised, and chapters on Dermatitis Herpetiformis, and Pityriasis Maculata have been added; while detailed descriptions of Lymph angioma circumscriptum, Pityriasis rubra pilaris, and Xanthoma diabeticorum are given; and a new chapter on Leprosy has been written. These changes, together with some additions to the therapeutical portions and other minor alterations, make the book in its present form more valuable. The scope of the work is essentially clinical, little reference being made to pathology or disputed theories. Almost every subject is followed by illustrative cases taken from the author's practice, and the reader is constantly reminded that he has before him a record of personal experience, while nothing is put forward to indicate that this experience has been unusually large. A feature of value to those having access to the large atlases, as well as for purposes of reference, is the plan adopted by the author of adding to each important chapter a list of the colored plates which illustrate the subject, together with their number and the atlas in which they are to be found. These lists are, however, not as full as one might wish, and some of the more recent productions are not referred to. Nine double-page colored plates are contained in the body of the work, but, as is so often the case, the subjects chosen for illustration are mostly instances of unusual diseases rather than the every-day affections which a student or family physician is likely to encounter. The picture of acne varioliformis conveys a rather faulty impression of the disease, as usually seen in this country and in Vienna. The illustrations of erythema multiforme and of lichen planus are very good, while that of lichen verrucosus is rather confusing. Besides a table of contents, and a complete alphabetical index, there is an author's index, containing the names of about two hundred and fifty of those to whose writings reference is made in the text, showing that, although the author has made his treatise largely one of personal experience, he has not hesitated to give the views of others, and has not neglected to give full credit for them.

The pages are filled with interest to all those occupied with skin diseases, and while the student can procure a more suitable text book for his purpose, the general practitioner will find the book of great value in matters of diagnosis and treatment. The latter is quite up to date, and the formulæ have been selected with care. The press work is excellent.

Prescribing and Treatment in the Diseases of Infants and Children. By Philip E. Muskett, Late Surgeon to the Sydney Hospital; formerly Senior Resident Medical Officer, Sydney Hospital. Philadelphia: P. Blakiston, Son & Co. 1891.

This is a handy little work on the therapeutics of children's diseases, which ought to be of great assistance to the young practitioner, and, indeed, to him of greater years and experience as well. The book is divided into three parts: The first is devoted to a consideration of the therapeutics and dosage, for children of different ages, of all the more important drugs used in modern medical practice. The second and main part contains directions for the treatment of the various diseases of infants and children; and in the third part are given a number of recipes for making barley-water, bread jelly, broths, whey, etc. A satisfactory index completes the work. The book ought to be a useful companion to Whitla's "Dictionary of Treatment."

The Book of Prescriptions. Containing upward of Three Thousand Prescriptions Collected from the Practice of the most Eminent Physicians and Surgeons, English and Foreign; comprising also a Compendious History of the Materia Medica, Lists of the Doses of all Officinal or Established Preparations, and an Index of Diseases and Remedies. By Henry Beasley. Seventh Edition. Philadelphia: P. Blakiston, Son & Co. 1892.

Those already acquainted with "Beasley's Three Thousand Prescriptions" need only be told that in this edition the editor has made a thorough revision of the work, throwing aside the obsolete remedies and substituting for them those of the present time, changing also the nomenclature of the drugs in order to accord with modern usage. One who is not already familiar with the work may learn what it is from the title. We need only add that the book is gotten out in very convenient form, in moderately small but very clear type, on thin paper, so that notwithstanding the vast amount of matter which it contains, it can be easily carried in the coat pocket and studied while the reader is going from one call to the other.

The Hydriatic Treatment of Typhoid Fever, According to Brand, Tripier and Bouveret, and Vogl. By Chr. Sihler, M.D., Ph.D. Cleveland, O.

A brief *résumé* of the application of water, principally cold, to lower the temperature. It is well written, and the treatment will no doubt, in time, meet with universal favor.

The Principles of Bacteriology: A Practical Manual for Students and Physicians. By A. C. Abbott, M.D. Philadelphia: Lea Brothers. 1892.

The book has no doubt been based on the course taken at the Hygienic Institute in Berlin. It is suitable for practical (elementary) work in bacteriology. It is carefully written and illustrated.

A Mean Sponge.—A wealthy Californian has recently been sued for the maintenance of his insane wife for fifteen years. He had placed her in an asylum and then disappeared. When found, he claimed that the asylum authorities can make him pay only for a short period, the rest of the debt being outlawed. He is reported to be worth over half a million dollars.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 4, 1892.

GEORGE L. PEABODY, M.D., PRESIDENT, IN THE CHAIR.

Discussion on the Treatment of Typhoid Fever.—The following discussion upon the treatment of typhoid fever, especially by the Brandt method, took place at this meeting and the two previous ones.

DR. J. WEST ROOSEVELT, in opening the discussion at the January meeting, said his remarks were intended to be only suggestive. In considering the advisability of resorting to a particular course of treatment, such as that of Brandt, the question arose, What were the symptoms which indicated danger? These might be divided into two groups: 1. Those suggesting more remote danger; 2, those suggesting immediate danger. Closely connected with the first was the question, What symptoms, if relieved, would lessen the danger to life? For example, did high temperature constitute a danger to life—one which, if it were relieved, would remove a danger to life? A further question related to the value of various forms of antipyretic treatment.

As to symptoms indicating danger, he regarded those connected with the temperature and the pulse as more or less distinct from those connected with the gastro-intestinal tract and with the nervous system. He would limit his remarks chiefly to those symptoms indicating danger connected with the temperature and heart-action.

There was no question, he thought, but what a patient might be killed by the temperature, if this reached a certain height, but the point to be determined was whether the temperature in a given case was injuring the patient, and whether lowering it would remove that danger. As to weakened heart-action, he thought it could be stated that the patient would be improved by relieving this, whether it depended upon high temperature or something else.

Dr. Roosevelt said he had not much to offer with regard to the so-called modern method of treating fever, the bath. Dr. Peabody, he said, had quoted the statistics of Brandt in support of that method in the treatment of typhoid fever, but there was a point which he thought should be inquired into if it had not already received consideration. He referred to the fact that in two army corps, of the same number of men, the cases of typhoid fever said to exist in the one where the Brandt treatment was carried out exceeded those existing in the other by double, and the mortality was only half as great, or four per cent. against eight per cent. Were not cases diagnosticated as typhoid fever in the one instance and not in the other?

But statistics might be made very delusive. For instance, out of 113 cases of typhoid fever treated in Roosevelt Hospital one could say there had been no deaths at all if he were to exclude such as Brandt had excluded from his statistics. In other words, out of 113 cases which entered the hospital before the fifth day not one died. But this signified nothing as to the value of the treatment, for the cases were treated in all sorts of ways. It was a mere coincidence that the mortality proved so low. In estimating the value of statistics it should be remembered also that no man had to treat an average. If, on the average, out of 1,000 cases 999 recovered and 1 died, the physician could not say, after having lost one case before reaching the thousand, that the next one and all the succeeding ones up to 1,000 would recover. He might lose several in succession. Figures, or statistics, varied greatly.

Observations in Bellevue Hospital.—DR. C. L. DANA said he could not quite agree with Dr. Roosevelt in his attitude toward figures; while statistics could be manipulated so as to show almost anything, yet they could also be used so as to throw a great deal of light upon a given question. Indeed the use of figures sometimes constituted the only way in which we could arrive at exact or approximate conclusions. The only objection to them was that they were sometimes handled wrongly, and might be collected in too desultory or careless a manner. If one had treated a thousand cases of a given disease with a mortality of only five per cent., and somebody else had treated, under like circumstances, another thousand cases by a different method and had lost twenty per cent., he thought one would be justified in drawing some conclusions from those figures.

In looking over the statistics of typhoid fever at Bellevue Hospital he had been impressed with the fact that during the last few years the mortality rate had been gradually diminishing. In 1890 the number of cases had been 18, with a mortality of 3; in 1891 14 cases, no deaths. When he was interne in the same hospital, in 1877–78, the mortality was thirty to forty per cent. The question arose whether this change was due to the nursing, the medical treatment, or the character of the fever. While he had not been able to get enough figures to throw a great deal of light on this question, yet through the kindness of Dr. Ewing, of the Health Department, he had received the yearly statistics of cases of typhoid fever reported to the Health Department, with the number of deaths since 1886. The number of deaths in 1886 had been 433; number of cases the last half of the year, 712; deaths in 1887, 421, cases, 1,004; deaths in 1888, 364, cases, 1,108; deaths in 1889, 391, cases, 1,414; deaths in 1890, 352, cases, 1,100; cases in 1891 to October 1st, 816.

It would seem, therefore, that the mortality rate from typhoid fever in the city had been steadily decreasing since 1886, whereas the number of cases had not decreased absolutely, yet it had decreased relatively to the population.

Referring again to the cases occurring in Bellevue Hospital the past year, he said a curious feature of the disease was that while in no case had it proved fatal, yet as a rule it had run a much longer course than formerly. Moreover, nearly one-third of the cases had shown a relapse.

Regarding treatment, during the three or four years prior to 1890 the tendency was pretty general to use antipyretics and stimulants. This was the practice a part of 1890 also, during which time three patients died, all of whom had received antipyretic drugs. The later cases had been treated by stimulants, baths, and intestinal antisepsis. Perhaps the sponge-baths and wet-packs had been the most characteristic features of the treatment. There had been practically no "tubbing." None of these cases had died.

In conclusion, he said that the record of the past year having showed such good results in the treatment of typhoid fever, although tubs were not used at all, led him to think that others may have been in error in attributing special therapeutic value to tubs where these had been employed. The milder character of the disease, the discontinuance of antipyretic drugs, the use of the wet-packs, sponging, and stimulants, including strychnia, and careful nursing would account for the diminished mortality.

Dr. Dana expressed his obligations to Dr. Hardenburg, one of the internes at Bellevue, for collecting and preparing the statistics.

DR. F. P. KINNICUTT thought that, owing to the varying intensity of typhoid fever during different periods, it was difficult to judge of the value of a given method of treatment by the general mortality rate of that period. He did believe, however, that we could judge of the effect of a specified method of treatment upon the general course of the disease, upon the symptoms, and upon the comfort of the patient. According to his own observation it had seemed that what had been called the Brandt method had produced beneficial influence upon the symptoms in general, and had greatly enhanced the comfort of the patient.

He had been impressed with its good effects upon the nutrition. Under this treatment digestion had remained normal throughout the entire course of the disease. The tongue had remained clean, and the movements had continued normal over and over again under the cold-water treatment, but, according to his observation, had seldom done so under any other method. He had also seen it bring about greater improvement in the mental condition than he had ever seen under any other treatment. It had also had a good effect upon the heart, and upon the general comfort of the patient. Those were facts which the doctor could judge of for himself in any given case, and he need not refer to statistics for proof of them.

Regarding modern antipyretics, he had for some time been convinced of their harm. His treatment was careful nursing, careful diet, and the cold bath in cases of more than moderate severity.

Typhoid Fever in St. Luke's Hospital.—Dr. Beverley Robinson said that some seemed to have advocated the cold bath as a treatment for *all* cases of typhoid fever. He thought this was an error. While it had a place, yet it had seemed to him a brutal treatment when applied as a matter of routine in all classes of cases and to all persons. He would not like to enforce a rule of this kind without regard to person or circumstance when he would not allow it to be applied to himself. Two years ago he was told by an able physician that he had typhoid fever. A request which he then made was that he should not be put into the cold tub.

Some months ago he had read a report of the treatment of typhoid fever by ———, of Paris, whose method consisted simply in urging the patients to drink large amounts of water, even to six or seven litres in the twenty-four hours. His results had been remarkably good. Being impressed with the reasonableness of the theory on which the method was based, namely, that it was through the kidneys as much as by any other means that the poison was eliminated, he continued to study the subject. He had found that about eleven years ago Meigs, of Philadelphia, had written very ably upon thirst as related to febrile affections. Other authorities had also written on the subject. It seemed to him that in the use of water internally we had a common-sense method, a rational method of treating typhoid fever.

The three chief theories which had been offered in explanation of the benefit derived from the cold bath were, 1, Lowering of the temperature; 2, influence on the disturbed nervous system; 3 (and this was the theory accepted by ——— and others), promotion of diuresis. The effect of increasing the urinary secretion was to lower the temperature and to aid in the elimination of waste tissue and the poison of the disease. But to take water internally would promote diuresis with just as great certainty.

The following statement of the treatment of typhoid fever at St. Luke's had been drawn up by Dr. L. F. Bishop, House Physician:

Following the recommendation of Dr. Beverley Robinson, all the patients have been urged to drink as much water as possible. The amounts taken have varied a good deal. The men took more than the women, and with less objection. The exact amounts taken are not recorded in very many cases, but the nurses have, as a rule, been faithful in urging the patients to take the water. It has seemed that this method of drinking abundantly of water has favored the well-being of the patients, and that there has been less nephritis and fewer cases of retention of the urine among them than is usual. The urine of these patients to whom water has been generously given has been noticeably large in amount. This fact has been most remarkable in the earlier days of the disease, because an increase in bulk of the urinary secretion during the latter weeks of a typhoid case is to be expected under almost any method of treatment.

Water has been given to typhoid-fever patients, in addition to seventy ounces of milk during twenty-four hours, to the amount of fifty ounces daily in some cases among the women (at least three in number), without occasioning dyspeptic symptoms or abdominal distention, or discomfort in any appreciable degree, so well as I can remember. The specific gravity of the urine decreased during the period of taking the water in large quantity in a ratio proportionate in amount with the fluid drunk.

In three cases the chlorine mixture of Dr. Burney Yeo, of London, was given. Of these one case died of perforation of the bowel, and two recovered. In the two latter cases the course of the disease was moderate in type.

In severe cases of typhoid fever the belief of the resident staff of St. Luke's is that cold baths diminish mortality. The sentiment among them is that in those cases where this treatment is not called for by the obvious gravity of the disease, and especially by high range of temperature, it prolongs unduly the duration of the disease, in this sense at least, that the subsequent prostration is more marked and recovered from very slowly.

My house physician states that cold baths were given with judgment. In those cases, usually mild ones, where cold tubbing was not systematically carried out, all got well, thus showing the reasonable basis of the conviction entertained, viz., that this method should only be employed under suitable conditions. In severe cases, as they seemed to be on admission to the wards, cold baths were promptly employed and some of the patients thus treated died.

The following are the causes of death: In one case the general severity of the disease. In two cases, owing to neglect or ignorance before admission (and in these instances although the tubbing was begun it had to be interrupted on account of the lowered vitality of the patients). In three cases, perforation of the bowel. All three of the latter were tubbed systematically. All three were exceptionally severe cases of disease. No deaths occurred from intestinal hemorrhage. No severe hemorrhage from the bowels took place. Small hemorrhages from the bowels were noted occasionally. These hemorrhages were a sufficient reason to intermit the tubbing for a while. It is not proven, however, that cold tubbing promotes intestinal hemorrhage, or if the latter unfortunately occurs, that it would be increased necessarily by continuance of the cold baths. Indeed it is thought that hereafter it may be wisdom to keep up the cold baths in very severe cases where they are being used, despite the hemorrhagic complication. In other words, it is not proven that under these circumstances the cold baths are necessarily injurious.

Granules of digitaline, one milligramme in each, and granules of arseniate of strychnine, half a milligramme in each granule, have been given, one of either kind every hour when the patient's condition has seemed to be critical, as manifested by a rapid and feeble pulse. This treatment has been kept up during several days on many occasions, without apparent harm to the patient, but, on the contrary, with obvious beneficial effects. Whenever death from cardiac exhaustion has seemed imminent, one of the granules of digitaline and one of strychnine were given every fifteen minutes. On more than one occasion the latter doses were given when the pulse-rate ranged from 150 to 170 per minute, and this treatment was continued until a reduction of twenty beats per minute took place. To accomplish this result the doses were sometimes repeated as often as every fifteen minutes during a period of several hours, *i.e.* (four to five hours). Afterward, the pulse had become slower and improved in quality, and the general condition of the patient seemed to be better. When the condition of the patient had improved the granules were of course given much less frequently. These granules (Chauteaud's) may be given dry on the tongue, and are swallowed by the patients without awakening them every time a dose of medicine is given.

Dr. Andrew H. Smith thought that to induce a patient with typhoid fever to drink much water was rational;

that it had the effect of reducing the temperature, of increasing the liquidity of the blood, of increasing the urinary secretion, of increasing the elimination of toxic and waste products in the body. He thought the physician should urge the patient to take plenty of water in addition to milk used as food, even though it might also prove necessary to resort to the Brandt treatment.

Further Endorsement of the Brandt Treatment.—Dr. W. Gilman Thompson had employed the Brandt method in forty eight cases of typhoid fever, and believed that, all things considered, it offered decided advantages over any other method with which he had had experience in hospital practice. The forty-eight cases had been treated during the past two summers in the New York Hospital, and the method of bathing employed had been essentially that of Brandt. Last summer he had used the water at a temperature of 70° instead of 75° F., leaving the patients in fifteen minutes. After removing them from the bath they were vigorously rubbed and given a warm drink. If necessary hot water was also applied. Out of the whole number there had been no accident or casualty attributable to the bathing. In only two instances did the bathing have to be discontinued because of the discomfort to the patient. Both of these were men who were very neurotic and complained against anything being done systematically. In one or two other instances the bathing was discontinued because of complications. Three of the forty-eight patients died. One died of pneumonia after having had seven baths. As soon as the pneumonia was detected the baths were discontinued. He did not think the pneumonia could be attributed to the baths. He was aware that some physicians did not cease the baths on account of complicating pneumonia. In one of the three fatal cases there was bronchitis, and in another hemorrhage. He did not think the bathing was responsible for the unfavorable result in any of the three.

The beneficial results were very marked in many instances. Especially in those which were brought in late, say about the tenth day, being in a dull, lethargic state. Where baths were employed patients were less likely to have delirium, they had a better expression, their general condition seemed to be improved. Some got used to the baths and liked them, while with a good many it was more or less of a struggle to keep up the bathing. Speaking further of the effects, he said the digestive functions were better, the urine was abundant, there was notable absence of toxic symptoms. Indeed he could hardly recall a case in which there was the typically typhoid condition—low delirium, brown tongue, etc. This had also been remarked by a number of his friends who had observed the cases. While often the temperature fell several degrees, yet in some it might not fall more than half a degree or a degree, yet the benefit would seem just as great. In other words, benefit seemed to be derived irrespective of reduction of the temperature. It was due, Dr. Thompson thought, to the tonic influence upon the nervous system. He had not found the duration of the disease shortened. It had been about the average. Nor had he found the treatment prevent relapses, there having been eight relapses among the forty-eight cases. The complications, however, had not been so numerous nor so severe; nor had sequelæ been so frequent as after other methods of treatment.

Typhoid Fever in New York Hospital the Past Six Months.—The President emphasized the importance of the statement made by Dr. Thompson, that the reduction of the temperature by the baths was not a measure of the benefit derived. He had repeatedly seen great benefit follow the bath in spite of the fact that the temperature was not brought below 105°, 106°, or 108° F. It was his custom to give the baths at 65° F., leaving the patients in for ten minutes He warned the beginner with this method not to think that because the temperature did not fall more than a fraction of a degree that therefore harm was being done and that it should be discontinued.

He did not stop the baths because of the existence of pneumonia. On the contrary, he had more than once used the baths through pneumonia complicating typhoid fever.

Dr. Peabody felt quite sure that, as Brandt himself had said, if we made it a custom to bathe patients early in typhoid fever we would bathe a good many persons who had not typhoid fever at all. It was important, therefore, to know whether in bathing a patient having a disease which was likely to be mistaken for typhoid fever we would do harm. As already stated, he had found pneumonia no contra indication, and he thought that ordinary tuberculosis or meningitis would not be. He presented the following: Total number of cases of typhoid fever treated in New York Hospital for six months ending January 1, 1892, 57; total number of deaths, 7; of relapses, 11; of spleen palpated, 25; eruption present in 40, absent in 17; tympanites marked in 5, absent in 31; epistaxis occurred in 13, absent in 44; intestinal hemorrhage occurred in 10, of which were bathed 4; hemorrhage caused death in 4 (all bathed); lobar pneumonia with hemorrhage caused death in one person, who was not bathed. One patient who had been bathed died of hemorrhage, lobar pneumonia, and perforation. One death occurred from perforation alone in a patient who had been bathed.

Of the total number treated—namely, 57—were bathed 42. Of these 42 there died 4. These 42 cases were bathed throughout the course of the disease.

The use of a long, soft stomach-tube to remove gas in cases of bad tympanites proved of great value. It was passed into the rectum and thence into sigmoid flexure, and, he believed, often into ascending colon. Large quantities of flatus were thus often discharged, to the great relief of the patient. In one patient this procedure was resorted to every three hours for several days at a time.

Typhoid Fever in the Presbyterian Hospital.—Dr. Andrew H. Smith said he had looked over the records of over one hundred cases of typhoid fever treated at the Presbyterian Hospital since 1882. This was not the entire number, for Dr. Thompson had just informed him that he had found records of 250 cases between 1882–90. Generally when the temperature had gone high the patient received the sponge-bath, not the tub-bath. More recently, especially in his own service, they had used the ice-coil over the abdomen a good deal as a convenient method of reducing the temperature. Antipyretic drugs had been used some, but only when the temperature ran high.

What seemed to him an objection in carrying out one particular line of treatment was the tendency which it begot to overlook differences between different cases. There were peculiarities pertaining to individual cases which should be taken into consideration in treatment.

It had seemed to him that the hospital interne usually became imbued with the idea that the more nutriment a typhoid patient took the better. If a typhoid patient had a furred tongue, frequent stools, a distended abdomen, the question should at once suggest itself whether he was being fed properly. Such symptoms could often be corrected by simply correcting the diet, and not giving the patient more than he could appropriate.

In the Presbyterian Hospital they had made considerable use of intestinal antisepsis, with, he thought, advantage. The mortality, including all cases, had been about fifteen per cent., and it must be admitted that they had received some very bad cases.

He thought the Brandt method elsewhere had been applied in more or less select cases, and that fact should not be overlooked in considering statistics. For instance, if a typhoid patient should have acute nephritis it was not likely he would be subjected to tub-bathing. So with cardiac trouble, etc. Yet this class of cases had not been excluded from the mortality rates following other methods of treatment in the Presbyterian Hospital. He inquired

what had been the mortality in hospitals in this country and in Europe where any routine method of treatment had been pursued.

Statistics of Mortality from Typhoid Fever.—Dr. W. G. Thompson said that during the War of the Rebellion there were statistics of 74,000 cases of typhoid fever; deaths, 35.6 per cent. Jaccoud had collected 80,000 cases, largely French; deaths, nineteen per cent. Murcheson, 27,000 cases; deaths, 17.5 per cent. Out of 17,000 cases collected in Vienna, the last few years, exclusive of those treated by cold baths, the deaths had been 22.5 per cent. In the Pennsylvania Hospital, for twenty years before the introduction of the Brandt method, the deaths had been 19.2 per cent. Brandt had collected 19,000 cases treated by all kinds of baths; deaths, 7.8 per cent. At the Presbyterian Hospital there had been, between 1882 and 1890, 250 cases, treated by various methods; deaths, 16.1 per cent. At the New York Hospital out of 501 cases treated between 1877 and 1889 the deaths had been 19.4 per cent. That was before the introduction of the tub bath. In 160 cases given by Wilson, treated by the Brandt method, the deaths had been five per cent. Hare had given seven per cent. as the death-rate from the Brandt method.

The President thought the only drawback to the Brandt method, as a method, was its expense. It required an abundance of fresh water, sometimes ice, and at least four able bodied men to apply it, two for day service and two for night service. At the New York Hospital one of the internes had devised what had been called the bed bath, which was the best modification of the tub-bath which he had seen. A rubber sheet was put under the patient, and the depression was filled with water which was kept cold with ice. This was much superior to cold sponging. He had also used the cold coil, and, while it was serviceable, it could not replace the tub. The latter was the most efficient method in reducing the temperature and in stimulating the nervous system. Replying to Dr. Smith's question, what objection was there to the Kibbe cot, he said the shock from pouring on water was much greater, and was frequently repeated as compared with the tub-bath.

Some Suggestions in the Management of Lung Fever.—Dr. Henry F. Walker read the paper (see p. 402).

Dr. Beverley Robinson thought it was a question whether the term lung fever was more appropriate than those already in use, pneumonia or pneumonitis. At present he would be sorry to have the public get the idea that pneumonia was likely to give the affectionate attendant the same disease. He thought it was highly improbable. He mentioned as a fact, for which he had no definite explanation, that when on visiting hospital wards for pneumonia he saw an unusual number of cases of that disease he felt worse for it, and in reply to his wife's inquiry what was the matter, he answered that he had, he supposed, seen a little more pneumonia than he should. The impression on his mind was that he had imbibed too much of the poison of pneumonia, although he had not acquired the disease.

He said that cases of pneumonia which had followed the grip had done better when he had given what seemed to be an internal antiseptic. The agent which he had chosen was a creosote mixture. He also used this sometimes by inhalation.

He thought some precautions against possible contagion of pneumonia might be taken without letting the family know the exact object, and thus avoid giving rise to undue excitement. Steam containing some antiseptic might be generated in the room. While it might be wise to take some such precautions, he must say that he saw no reason for regarding pneumonia as more contagious or infectious than any catarrhal affection of the respiratory tract. It called for greater precautions simply because it was a severer disease. When a simple cold affected one member of a family the entire family was likely to become affected. Dr. Robinson thought that while some of his remarks might not sound very scientific, yet we would have to regulate our conduct somewhat according to the people's view of common sense, if we would not get into a position which it would be difficult to maintain.

Dr W. G. Thompson was quite in accord with what Dr. Walker had said with regard to the infectious nature of pneumonia, but more particularly in cases associated with grip. Last spring after the fire had occurred in the Presbyterian Hospital they were compelled to crowd the wards, and medical and surgical cases were put into the same room. During this time a number of cases of pneumonia were admitted on the medical side, and the disease was then acquired by patients on the surgical side who had been in the hospital for some time. Altogether there were ten or twelve cases of pneumonia which originated in the hospital among patients who had come in for some other trouble. They were obliged to clear the ward and disinfect it thoroughly, whereupon the trouble ceased.

Dr. Ewart, of London, expressed his interest in the subject, but said that personally he had never come across an epidemic of pneumonia nor met with an instance of known contagion or infection. On reading over the observations of other men it was hardly possible not to believe in the facts stated. It had seemed to him that the cases of pneumonia occurring in connection with epidemic influenza had been nearly altogether of the lobular type, and he thought light might be thrown on the question of the contagiousness of pneumonia by observing the form present when the disease existed in connection with epidemics.

The Same Rules Apply in Pneumonia as in Phthisis.—Dr. A. H. Smith thought the same rules applied with regard to infectiousness in pneumonia as in phthisis. In lobar pneumonia we had a specific disease, one due to a specific microbe, and the question of contagiousness was a question of the transplantation of that microbe from one individual to another. It might be possible for the transference to take place immediately by passage of the microbe from the sick to the well through the air, but more likely it usually took place, as in phthisis, by dried sputa floating in the air. The danger was less where but one patient was sick and was confined to a single room. It was much greater in an hospital where there were constantly many patients.

He thought Dr. Robinson had suggested that one could get a little, but not necessarily the whole disease. This view was hardly tenable. A man either had pneumonia or he had none. Nothing annoyed him more than to hear that So-and-So was threatened with pneumonia. He thought it would be as well to say that he was threatened with small-pox or scarlet fever. Pneumonia was a positive thing; it was there or it was not there. He did not believe that a patient was ever rescued from an impending attack of pneumonia by anything that had been done for it.

Dr. Robinson said he did not wish to dispute the point raised by Dr. Smith, but he wished to say most decidedly that one might feel the impression of the atmosphere which he breathed. The feeling was not the same, for instance, in a ward where there was much pneumonia or diphtheria as in one free from sick people.

Dr. Smith added that for eight months of his service at the Presbyterian Hospital, in 1889, twenty-one patients were admitted with pneumonia, only three of whom died. One was nearly moribund when admitted.

Pneumococcus in the Dust.—Dr. H. M. Biggs recalled bacteriological studies of a German made three or four years ago which revealed pneumococci in the sputa and dust upon the floor in hospital wards.

We Don't Know it All.—Dr. Robinson thought that we did not yet know all about the etiology of pneumonia and other diseases called infectious. At one time he was exposed in the course of his studies to diphtheria, was in bad health, and in what one might suppose to be

the best condition for acquiring the disease, whereas on another occasion, when in good health and there was no reason why he should be susceptible, he did contract it. With regard to pneumonia, he would defy even the best microscopist to state positively what was its cause. He would also defy the best diagnostician, in many instances, to say whether what existed was a bronchitis or a pneumonia, a lobar pneumonia or a lobular pneumonia. In view of changing opinions on medical and surgical subjects the last few years, he thought it was unsafe with our limited knowledge of the subject to declare positively that a patient either had pneumonia or had not.

The President expressed belief in the infectious nature of so called lobar or croupous pneumonia. A number of instances had come under his personal observation pointing to infection. For instance, a member of a family would acquire pneumonia, the only time the disease had been in the house for a generation, and within a week or ten days another member became affected. The late Dr. M—— died of pneumonia, and within a week Mrs. M—— took the disease and also died. In a German village pneumonia had not existed for a winter; then it appeared in a house of five or six persons, most of whom died of it. Regarding the pneumococcus, he agreed with Dr. Robinson that at present we knew less about it than we supposed we did a short time ago. He did not doubt, however, that pneumonia was a specific disease which was likely to spread, but which was less likely to spread than some other infectious diseases. He had not seen it spread to hospital attendants, nor in definite wards.

Dr. Walker remarked, in closing the discussion, that he was perfectly willing to admit that a cold in a family was likely to spread; that it was contagious to a certain degree, but one might not be willing to alarm a family about that when he would risk creating some alarm in order to prevent the spread of so fatal a disease as was pneumonia. He thought measures could be adopted for the protection of others in the house without causing undue alarm.

Cure of the Cocaine Habit.—Dr. Robert Abbe related a case of pure cocaine habit in a young man who was able to throw it off by sheer will-force. When twenty-three years of age he was member of a church choir, and once when he contracted a cold his teacher advised him to use a little cocaine for its relief. It so improved his voice that he continued to use it. Being a draftsman, he also used it to enable him to sit up at night while drawing. At last he was snuffing into the nose two ounces a day of a four-per-cent. solution. Under the influence of the drug he could sit for hours at drawing or walk miles without fatigue. After a time he became morose, lost flesh, spent all the money he had for the drug, and got more on trust. After a year and a half his family induced him to see Dr. Abbe, who advised him to make a supreme effort to rid himself of the habit. He went on a farm, engaged in the hardest labor from early till late, regained his health, and lost all desire for cocaine, the use of which he had discontinued all at once.

The President remarked that it had been denied that the cocaine habit ever existed alone. Usually it was associated with the morphine habit.

Dr. Abbe said this young man had never used morphine nor stimulants. He smoked.

The President said that a few years ago he had seen a case of combined cocaine and morphine habit in a physician in whom it had caused a marked hallucination. For months he feared that burglars would enter the house, and he barricaded the doors with furniture, etc. He also thought that the cocaine was coming out in crystals on his skin. On other topics he talked rationally. He took the drug subcutaneously until he died from its effects.

Dr. Charles L. Dana said that the simple cocaine habit was rare, and therefore he would mention a case similar to that of Dr. Abbe's which he saw with Dr. Fitch. A young man, aged about twenty-three, began the use of the cocaine spray at the advice of a rhinologist, continued it, and acquired a morbid habit. He increased the amount until he reached forty grains a day, which seemed to be about the maximum amount which habitués usually reached. He had no delusions or hallucinations, but became entirely irresponsible and useless. Finally he reached a state bordering on dementia, and they committed him to an asylum for the insane. It seemed that a common way of acquiring the vice was by the use of the nasal spray at the advice of a physician or other person.

Collapse Following the Use of Cocaine.—Dr. Samuel Sexton inquired of the members whether they had observed depressing effects from the use of cocaine about the mouth or nose. He had had considerable experience with the use of a four-to-five-per-cent. solution in the middle ear, and in a number of instances had witnessed marked collapse. The patient did not become unconscious, but was unable to sit up.

The President said there was considerable in medical literature relating to sudden collapse coming on from the use of a spray of cocaine in the nose, etc., and the explanation which had been offered was that it was attributable to hysteria, or an impression on the nervous system; that it occurred too suddenly to be the result of absorption of the fluid into the circulation.

Dr. Sexton thought that in whatever way the effect was produced it was directly traceable to the drug.

Dr. Robinson had seen patients faint away on receiving a spray of four- or five-per cent. solution of cocaine into the nose. The effect was not one of nervousness at all. He had witnessed it at least four or five times within three or four years.

Dr. Dana thought it was more likely a reflex phenomenon.

Dr. A. H. Smith had known of a death recently from the introduction of cocaine into the urethra preparatory to incising a stricture.

The President said that in the case referred to by Dr. Smith twelve grains had been injected, which was a toxic dose, and perhaps sufficient time had elapsed for it to become absorbed.

Dr. Biggs said that the injection of a little cocaine into the veins of a dog would stop the heart instantly, yet ordinarily it was not easy to stop the pulsations of the heart.

Dr. H F. Walker had made a hypodermic injection of ten drops of a four-per cent. solution of cocaine in a case of sciatica, shortly after cocaine had come into use. The patient became pulseless and death seemed imminent. Since then he had made applications to the nose in the same patient, always with the result of violent cardiac palpitation after a small amount had been used.

Dr. Abbe said that surgeons regarded cocaine as less safe when used about the mouth and face than when used elsewhere. He had seen what seemed almost fatal collapse follow injections of ten or twelve drops of a two to four-per-cent. solution about the face.

A Dime Museum Wedding.—A marriage was celebrated not long ago, in a town in Alsace, between Miss Ariel Lillipuzian, three feet two inches tall, and Mr. Hedley, six feet four inches in height. The groomsmen were Mr. Hubert, who was born without arms, and signed the wedding contract with the pen between his teeth, and Captain Dallas, who rejoiced in a height of eight feet. The bridesmaids were Miss Balatra, a lady of ample proportions who turns the scale at one thousand three hundred and twenty pounds, and La Satanella, the human salamander. All the parties belonged to the side-show of a circus giving performances in the place.

A Wise Determination.—Koch has written to a Swedish physician that he will not sell nor describe his improved tuberculin until he shall have tested it in private beyond all chance of doubt.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, January 11, 1892.

WILLIAM T. BULL, M.D., CHAIRMAN.

Election of Officers.—Dr. Joseph D. Bryant was elected Chairman for the ensuing year, and Dr. W. W. Van Arsdale, Secretary.

Discussion upon Intestinal Surgery.—The discussion upon this subject took the form of presentation of specimens and patients by several members, and the reading of papers by DR WEIR and DR. ABBE

Resection of the Rectum.—DR. WILLY MEYER presented a man on whom he had, a year ago in October, performed resection of the rectum by Kraske's method for cancerous stricture. The result had been quite satisfactory; the man made a good recovery, had perfect control over the passages, and nearly perfect control over gas.

Epithelioma of the Sigmoid Flexure.—DR. B. F. CURTIS showed a specimen illustrating circular suture of the resected gut similar in appearance to one he had mislaid. His patient had suffered from chronic constipation of some months' duration, and he found, on operating, a circular epithelioma in the sigmoid flexure, which he exsected and joined the ends of the gut together by circular suture. The patient died within forty-eight hours, of suppression of urine and nephritis. There had been absolutely no leakage at the intestinal wound.

Resection of the Rectum for Cancer.—DR. PARKER SYMS related a case in which, over two years ago, he had performed resection of the rectum according to Allingham's method, taking away four inches, for cancer. The woman did well over a year, and at the end of two years appeared again, when there was found a large cancerous tumor which necessitated removal of the posterior wall of the vagina along with the cancerous portion of the rectum. Kraske's method, or resection of the sacrum, was resorted to on this occasion. The operation was done last March, and the patient had been well since. He remarked upon the advantages of preliminary colotomy, which was also resorted to in this instance.

Resection of the Sigmoid for Cancer.—DR. SHUNK presented a specimen and related the case of a woman, aged sixty, who had had symptoms of obstruction, evidently due to a tumor situated at about the sigmoid flexure of the colon. Her condition being low, he performed preliminary colotomy; she then improved much, and at the end of six weeks the diseased portion of gut was drawn out of the opening made for the artificial anus and cut off. This left the lower segment too short to permit of anastomosis, and consequently both ends were drawn up to the opening and stitched in. The patient did well for eight days, and then sudden and violent gastro-enteritis developed, of which she died within twenty-four hours. The autopsy showed new-growth obstruction at the pylorus and great dilatation of the stomach.

THE CHAIRMAN also presented a specimen of cancer of the sigmoid flexure which had been operated upon for obstruction, with a fatal result

Laparotomy for Fecal Fistula following a Strangulated Umbilical Hernia—Cure.—DR. WEIR presented a patient, aged fifty four, who had had strangulation occur some three months previously in an umbilical hernia of large size and of long duration; as a result the several openings were said to have been formed from which pus and fæces came. There was, when first seen by Dr. Weir, an umbilical hernia, the size of one's fist, and on its right side where the level of the abdominal wall was reached was a single fistulous opening, the size of a large lead-pencil, through which were continually leaking fluid fæces. Several scars over the hernia marked the sites of the other fistulas. The operation consisted in opening the peritoneal cavity outside and above the fistula, and thence after locating the latter the incision half encircled on the same side the hernia. This gave a good view of the parts. The fistulous track was recognized as running into the small intestine. This was temporarily clamped near the bowel and cut away from the skin. By so doing the incision was now liberated so that the contents of the hernia, consisting of coils of matted small intestines, could be uncovered. These were carefully separated from each other and from the sac-wall, and replaced in the abdomen. In one place there had evidently been a perforation. The incision was now carried around the left side of the hernial mass and the latter skin. Some flattened out omentum and sac removed entirely, leaving an opening some two inches in diameter. Attention was now given to the fistula. The loop of intestine containing it, which had been held to one side, was now farther drawn out of the abdomen, and the remaining portion of the track cut off nearly on a level with the bowel and the entrance into the bowels exposed. The actual opening into the lumen of the gut was about one-half of an inch in diameter. The mucous membrane was freshened and sutured, and the opening finally closed by two layers of interrupted silk Lembert sutures. The umbilical opening was also closed by Macewen's heavy chromicized catgut sutures, supplemented, as the parietes were very thick and fat, by four or five silk sutures going through all the layers of the abdominal walls save the peritoneum which was closed by the ordinary catgut sutures. Recovery without reaction. Bowels moved on fifth day spontaneously. Patient sat up on the twenty-third day. One month from operation was sent to his home in the country. No disposition to recurrence of the hernia. Directed to wear a retentive bandage but not a pad.

Intestinal Anastomosis without Rings; Between the Ileum and the Sigmoid Flexure for Intestinal Obstruction; Neoplasm; in the Transverse Colon.—DR. WEIR presented the patient and read the history (see p. 399).

Gastro-Intestinal Anastomosis and Pylorectomy.—THE CHAIRMAN presented the specimen as illustrating to what extent contraction might take place in the opening made by gastro intestinal anastomosis in the course of ten days, during which time food had passed through the opening. The opening had been made with the use of Abbe's catgut rings, three inches in length, and had contracted down in the ten days so that it would just admit the index-finger. This patient was subjected to pylorectomy, at the end of ten days, for cancer of the pylorus, but died.

Operations in a Case of Cancer of the Sigmoid Flexure.—THE CHAIRMAN presented another specimen, in contrast with the former one, as to the amount of contraction of the intestinal opening after anastomosis. The catgut rings had measured about two inches and a half inside, and at the end of two years the opening had remained sufficiently large to admit of normal function of the bowel. The case was one in which he first performed colotomy preliminary to removal of a cancerous stricture in the sigmoid flexure. Being unable to induce the artificial anus to close after two years, he performed intestinal anastomosis, and the woman lived in comfort two years longer. Then symptoms of obstruction occurred, which he supposed were due to contraction at the point of anastomosis, but laparotomy showed it to be due rather to matting of the coils of gut at this point and their displacement. At death the opening at the point of anastomosis was found still of considerable size. The case was also interesting in the fact that cancer of the sigmoid flexure had been removed five years before, and no recurrence had taken place there or elsewhere.

Several Cases of Unusual Interest in Intestinal Surgery.—DR. ROBERT ABBE read the paper (see p. 365).

DR. JOHN A. WYETH was of the opinion that all would agree with the reader that there was nothing simple about intestinal anastomosis; it was a very serious procedure. He had always expressed the opinion in discussions on the subject that terminal anastomosis was

better than lateral, and he was glad to learn that Dr. Abbe seemed of this opinion at present. The strongest objection to lateral anastomosis was that the opening would contract, and the operation was likely to prove only a temporary salvation to the patient.

Dr. B. F. Curtis was also glad to learn that Dr. Abbe had given up rings and plates, and come back to simple suture. As to a choice between lateral anastomosis and terminal anastomosis, he was of the opinion that contraction would take place in the lateral form whether rings were used or not, and therefore he at present favored circular suture, which, so far as experience up to the present had gone, showed less contraction. Circular suture was the more difficult operation, but not so much more difficult where the continuous suture was employed, as has been done successfully of late by German surgeons. He differed from the author in the view that difference in size between the two ends of the gut made terminal anastomosis impracticable; where it existed one had only to cut one end obliquely, or slit it longitudinally in order to make the distance of suturing equal and leave no puckering.

Dr. J. D. Bryant remarked that the delays which so often occurred in connection with intestinal obstruction resulted in impairment of the tissues by over-distention, congestion, and catarrhal changes, and greatly jeopardized the success of an operation. This argued in favor of prompt action.

Dr. Weir remarked that we did not know yet but what the opening could be made so large in lateral anastomosis as to avoid any danger of undue contraction; that the results of this form of anastomosis were, so far as statistics yet went, better than those of circular union.

Dr. Kammerer had used the rings and plates four times, and had also performed anastomosis several times by ordinary sutures, and thus far he much preferred the ordinary suture. As Dr. Abbe had said, ten or fifteen minutes added to the duration of the operation ordinarily made little difference. As to resection of the rectum he had performed this operation several times, but never got complete primary union; there always occurred more or less fecal fistula at the posterior part.

Dr. Willy Meyer thought the question whether lateral anastomosis or circular suture was best, was still an open one. He briefly recited his experience with Kraske's operation in four cases of stricture of the rectum.

Dr. Dawbarn expressed decided preference for lateral anastomosis and the use of plates. The saving of ten or fifteen minutes was very important. The potato plates were, he believed, safer than the catgut, for they remained firm for several hours in warm fæces, whereas the catgut rings softened very much within an hour. It was almost impossible to introduce the ordinary suture without passing the needle entirely through the walls of the intestine. An important obstacle in the way of circular suture was the mesentery junction.

Dr. Abbe said that on the living human subject he had experienced no difficulty in introducing the sutures without danger of going into the hollow of the intestine. Five inches of raw potato was a serious objection to the plate, since one knew not how much irritation it might give rise to. He thought circular suture would probably prove better where a pathological state or difference in size between the two ends did not make it objectionable, as in the cases where he had resorted to lateral anastomosis without plates.

Mingled Faith and Patriotism.—"I don't want any castor-oil." said a sick little Boston boy, petulantly, "and I won't take it."

"Why, Horace," expostulated the mother, "don't you know that castor-oil is made from beans?"

And the little boy, whose faith in his mother is perfect, took the dose and feebly asked for more.—*Indianapolis Journal.*

Therapeutic Hints.

For Asthma:

℞. Ext. euphorbiæ piluliferæ.. ..... ℥iij.
Nitro-glycerine ..... gr. $\frac{1}{100}$
Sodii iodidi..... gr. ij.
Potas. bromidi..... gr. ij.
Tr. lobeliæ..... ℥ij.

M. Sig.: To make one dose which may be doubled or tripled and used three times a day.—*Therapeutic Gazette.*

For Uric Acid.—German physicians are using piperazin as a solvent for uric acid. Dr. J. H. Brit gives it in doses of 15 or 30 grains in water or in the following mixture:

℞. Piperazini puri..... gr. xv.
Aq. destil..... ʒ v.
Syr. aurantii cort..... ʒ v.

M. Sig.: To be used during the day.

Acute Rheumatism:

℞. Euonymin..... gr. ¼
Podophyllin..... gr. ⅛
Aloin..... gr. ⅛

M. Ft. pil. no. 1. Sig.: Give night and morning as necessary.

Give alkalies till saliva is alkaline. Following is useful combination:

℞. Lithii benzoatis..... ʒ ss.
Sod. brom.,
Potas. carb.....āā ʒ ij.
Potas. acet..... ʒ jss.
Sodii phos ..... ʒ ss.
Syr. zingib.,
Aq. menth. pip..... ..āā ad ʒ vj.

M. Sig.: ʒ ij. to ʒ ss. in water, four to six hours after meals.

For antipyretics use antipyrine gr. x. and digitalis gr. j. combined. For analgesics use phenacetin or antipyrine, and if necessary a combination of morphine, bromide, and chloral. Give alkaline mineral waters copiously. Give tonics, the following being excellent:

℞. Tr. ferri chlor..... ʒ iv.
Tr. nuc. vom.,
Ac. phos. dil..... āā ʒ ij.
Syr. aurantii cort..... ʒ j.
Elix. calisaya.....q. s. ad ʒ ij.

M. Sig.: ʒ j. in water t.i.d. before meals.

If heart weakens, use following:

℞. Spts. ammon. aromat..... ʒ iij.
Ammon. carb..... ʒ j.
Tr. cardomom..... ʒ i.
Tr. nuc. vom..... ʒ iij.

M. Sig.: ʒ j. t.i.d.

For topical application use:

℞. Tr. aconit. rad.,
Tr. arnica.....āā ʒ ss.
Chloroform..... ʒ j.
Tr. saponis camph..... ʒ ij.

M. Sig.: Apply locally.

Exclude nitrogenous foods. Salicylates, baths, and massage are of doubtful value.—F. Le Roy Satterlee, M.D.

Phthisis.—Creosote is an excellent adjuvant to other remedies in the treatment of phthisis. In Bellevue Hospital, where it is extensively used, it is put up in a liquid with syr. zingib. and elix. cinchona, or in a pill with bismuth. In capsules alone it is apt to irritate the stomach. An excellent method of using it is with an inhaler, a cheap and efficient form of which is that of Dr. Beverley Robinson. For inhalation it is prescribed with chloroform and alcohol.

Diphtheria. — Professor William H. Thomson treats diphtheria with Smith's solution of bromine. Apply it to the throat, diluted, one part to eight parts of water, and give it internally, diluted, and according to age, every two or three hours.

For Tape-worm.—After a day's fast give, at 6 A.M., one ounce Epsom salts; at 9 A.M., ten grains calomel; at 9.30

A.M., six ounces decoction pomegranate; at 10 30 A.M., four ounces of same, and then look out for the worm. First trial may be unsuccessful, but very rarely the second. Decoction of pomegranate is made by adding eight ounces of fresh bark to one quart of water, boiling down to ten ounces and then straining.—W. M. CARPENTER (deceased).

Thyol Preferable to Ichthyol.—Dr. Buzzi prefers thyol to ichthyol, for the reason that it is a chemical body synthetically produced, while ichthyol is subject to variations and a mixture about which little is known. Taken internally, it does not produce a bad taste in the mouth, a disagreeable odor, nor repeated belchings as ichthyol does, and it is not so expensive as the latter. It can be given in doses of three centigrammes to a gramme three times a day. Poisonous effects have never been noted. Externally, it finds the same range of usefulness in skin diseases as does ichthyol, and can be used in the same way.—*Deutsche Med. Zeit.*, January 28, 1892.

For Chronic Eczema of the Scrotum.—Dr. Fournier recommends, as the best treatment for chronic eczema of the scrotum, that the patient wear continually an india-rubber suspensory.

Hysteria:

℞. Ol. terebinth.,
Ol. ricini . . . . . āā ʒ ss.
M. Sig.: In the morning once a week. Or the following:

℞. Pulv. assafœtidæ . . . . . ʒ ij.
P. myrrhæ . . . . . ʒ j.
Sodii salicylat . . . . . ʒ j.
M. Ft. capsules No. xxx. Sig.: One two hours after eating, and before retiring.

℞. Kal. brom . . . . . ʒ vj.
Spts. frumenti . . . . . ʒ viij.
Elix. ammonii valerian . . . . . ʒ xij.
M. Sig.: Take tablespoonful with the above capsules. If bowels continue constipated, use colocynth ext. co.

W. H. THOMSON.

Mumps	0	0

Relief of Eye Pain by the Hot-box.—Dr. Chisolm, writing in the *Annals of Ophthalmology and Otology* for January, 1892, says that two years since, when visited by a medical friend from Japan, his attention was called to a small flat hot-box which was said to be in universal use in that country as a pain-killer. The box was a little smaller than the hand in length, breadth, and thickness. It was slightly curved in shape as is the hand when it begins to close, so that the concavity can apply well to the rotund parts of the body. The box was made of very thin sheet copper or tin, perforated with a few small holes to allow of the admission of air. Over the top was a sliding lid fitting accurately into the groove. The metal box was covered with colored muslin. The heating power was a cartridge, resembling a large Chinese shooting-cracker. It was made of powdered charcoal firing wrapped in paper. It was about four inches long, as large in circumference as the index-finger, and would burn under slow combustion for nearly three hours. One of these charcoal packages, when lighted and closed up in the box, would burn slowly owing to the small amount of air admitted through the perforations in the metal, and would keep up a temperature about 120° F. The metal was so thin that the box had but little weight. These pain-relieving boxes are to be found in every home in Japan, and are in universal use for the relief of pain wherever located.

Hot cloths are so soothing in the relief of eye pains that Dr. Chisolm determined to experiment with this hot-box from Japan, and he says that it is now one of his most trusted agents for the relief of pain in many eye diseases, such as iritis, scleritis, corneal ulcers, and glaucoma. His method of application is as follows: After the fuse has been lighted and the box has become warm, it is enveloped in the folds of a handkerchief and secured to the head by the ends of the handkerchief. A little loose cotton applied over the closed eye fills up the socket and allows the heat to be transmitted directly to the painful organ. The handkerchief protects the face from the edges of the hot box. Once applied it needs no renewal for two or three hours. In many cases the relief of pain, the author says, is magical. In old persons he has avoided the necessity of removing painful eyes lost by glaucoma by the use of this hot box; in some cases in which, previous to its application, the disease had resisted both iridectomy and medication, local and general. The Japanese hot-boxes and cartridges can be found at all Japanese stores, and are also kept by many druggists. Dr. Chisolm says that they commend themselves for their convenience, simplicity, economy, cleanliness, and efficiency as an application for the relief of pain, and finds in them the most valuable method of applying dry heat as a remedial agent.

Ventilation of the Holds of Ships.—A very important question concerning the ventilation of holds in ships has been raised by a letter addressed to the Secretary of Lloyd's. This letter is written by Mr. J. Stanley Metcalf, Consulting Secretary to the North of England Protecting and Indemnity Association. Formerly the hatches were the only means of ventilation for the holds of ships, and these were only lifted off when the weather was fine and dry. Porous cargo had therefore no opportunity of absorbing moisture from foggy or damp weather. But now there are large cowl ventilators, utilized in all weathers, and which let down on to the cargo any amount of damp air. This is readily absorbed, notably by such substances as jute. On the other hand, the ventilation is not sufficient to dry the cargoes. An experiment to illustrate this fact is suggested. If we place dry tobacco in a jar with a small hole in the lid and expose the jar to humid air, the tobacco will become quite damp, and then, even if removed into a dry, warm room, it will remain moist for a long time. Though the small hole, like a cowl on a ship, suffices to let the dampness in, it does not suffice to dry the tobacco. But if we remove the lid of the tobacco jar, or, in the other case, the hatchway of the ship, when the temperature is warm and dry, then the tobacco or the cargo will be in a position to be dried by the evaporation of the moisture. We need hardly point out how injurious to the cargoes and to the health of the persons on board such dampness must be. Where there is a vegetable cargo, such as potatoes, onions, etc., the probabilities are that the damp will cause fermentation, and occasion nor merely the destruction of the cargo, but a foulness of atmosphere dangerous to health. This is so much the case that captains sometimes close all the cowl ventilators as soon as they are at sea and away from the control of the port sanitary authorities. Evidently the regulations as to the ventilation of the holds, where cargo alone is packed, require, in the face of these facts, careful revision.—*The Lancet.*

CASES OF APPENDICITIS, ILLUSTRATING DIFFERENT FORMS OF THE DISEASE, WITH REMARKS.

BY CHARLES McBURNEY, M.D.,

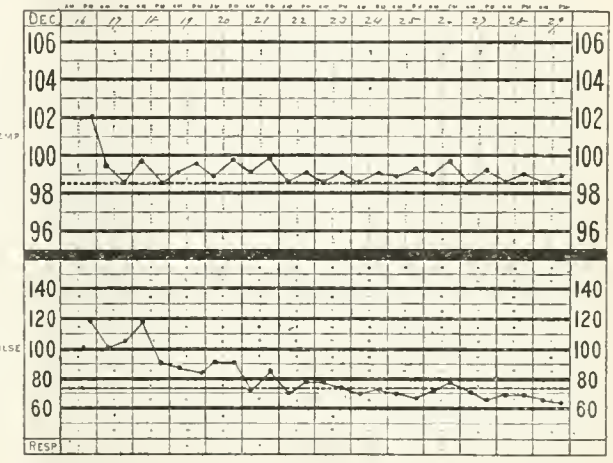
SURGEON TO THE ROOSEVELT HOSPITAL, NEW YORK CITY.

MR. PRESIDENT AND FELLOW-MEMBERS OF THE ACADEMY: I feel that I need make no apology for introducing once more the well-known topic of appendicitis, for I know of no other which, at the present time, commands and deserves to an equal degree the deep interest of both the medical and surgical members of our profession. Formerly a comparatively rare disease, because we failed to recognize its every-varying expression, it is now common enough, simply because we have learned to know its changeable face. Here and there it has seized a dear friend or a stranger patient, and from our midst it has carried away those whom we would gladly see with us again, and many of us, as we look back into the past, can now recognize distinctly the retreating form of the intruder whose shadow only was at that time visible. Within the last five years we have learned much about appendicitis, its frequency, its mortality, its insidiousness, and its power, and not a few, more bold than the others, have torn from it its amiable but disingenuous masks of typhlitis, perityphlitis, and the like, which still, however, deeply interest some writers, notably our English confrères. But though we have learned much, we have still much to learn, and the variety of opinion that exists as to the treatment of this disease proves that there is still ample opportunity to reap profit by further discussion. I do not intend to-night to present a statistical paper of experience to support some general conclusions, but rather to present to you a few recent cases over which we may freely consult. I have brought here the records of these only, because they in themselves cover a sufficiently wide ground, and because coming close together, within the comparatively short period of fifteen days, they represent a section of actual practical life, and so possess some individual interest. I have included all the cases seen by me within the period referred to from December 6, 1891, to December 21, 1891.

CASE I.—Miss H——, a rather delicate young lady, aged twenty-three, a patient of Dr. R. P. Francis, of Montclair, N. J., has had during the past four years a number of attacks of abdominal pain of short duration, which were regarded and treated as "colic." In February, 1891, she had an attack in which she was attended by Dr. Francis, who recognized the signs of appendicitis clearly defined. The constitutional signs were slight, the temperature at the highest being 99.8° F., and the illness lasted only four or five days, when all signs of appendicitis disappeared until the middle of October last. From that time some tenderness was felt in the right iliac fossa, and for a number of days the patient made use of a hot-water bag from time to time to relieve pain. On December 14, 1891, in the evening, decidedly increased pain was felt in the lower abdomen, mostly in the median line, and but little in the right iliac fossa. The temperature was then 98.2° F., and the pulse 100. The bowels had moved in the morning. One-eighth grain of morphine was given twice, and during the night nausea and vomiting occurred. The next day the local signs of appendicitis were well marked, but the pulse and temperature had not risen. On the 16th, in the morning, the temperature was 99.2° F., the pulse 84, and nausea had disappeared.

At noon sudden severe pain was felt in the right iliac fossa, and extreme sensitiveness to the slightest touch was noted to exist at the situation of the base of the appendix. Temperature and pulse remained normal. Three hours later the tenderness was less, but the temperature was 100.5° F., and the pulse rate 100. At 6 P.M. the temperature was 102° F., and the pulse 120, and nausea was continuous. Small doses of morphia and atropia were administered.

On December 17th, at 4 A.M., a second attack of sudden severe pain was felt in the right iliac fossa. The abdomen became very slightly distended, but the temperature was found to be only 99.5° F. At three o'clock in the



afternoon I saw the patient for the first time, together with Dr. Francis, Dr. L. F. Pinkham, and Dr. C. T. Parker. The patient's temperature was still only 99.5° F., the pulse excited at 110. Nausea was present, and the abdomen was slightly rounded. At a point two inches from the anterior superior iliac spine, in the direction of the umbilicus, great sensitiveness to pressure existed. Close to the spinous process, and along the outer fourth of Poupart's ligament, a small, very sensitive tumor, about one and a half inch in length, could be felt. The diagnosis made was perforative appendicitis, with suppuration already begun. Operation was done at once. The incision was made in the long axis of the tumor, about one inch away from the anterior spinous process.

The appendix was readily found. It lay directly beneath the incision, was half gangrenous, perforated at its middle, and contained a fecal concretion the size of a cherry seed. About two drachms of pus surrounded the appendix, and this fluid was well prevented from entering the general cavity by a uniform abscess wall. No injury to the abscess wall occurred during the operation, and the appendix was ligated with catgut and removed, the stump being disinfected with the cautery. The cavity was thoroughly cleansed and packed with iodoform gauze, without drainage-tube and without irrigation. The subsequent history of the case is extremely simple, and is well told by the charts. No outward symptoms of any kind occurred. Dressings were made on the 20th, 23d, 26th, and 30th, and so on. The bowels moved by

enema on the third day. The patient was able to get up and walk on the thirtieth day after operation, and has remained in perfect health since.

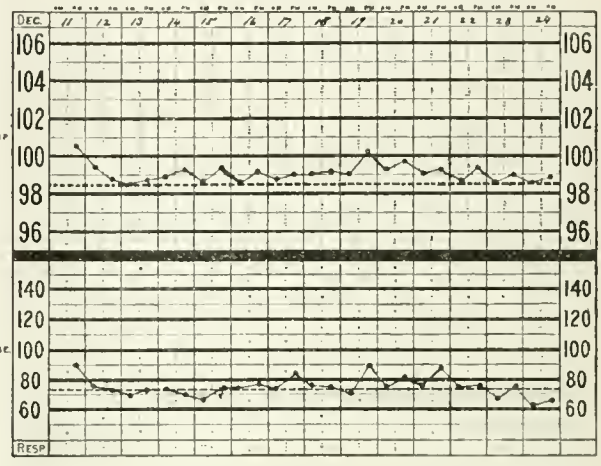
This case represents a class of cases of quite common occurrence, in which during the first twenty-four hours of the illness it is difficult to satisfy one's self as to whether the attack will subside under rest, a little anodyne, and cold or hot applications, or whether a process has begun whose natural history is to develop more serious conditions. During this early period, with such signs as have been described, no careful man would think of insisting that for the treatment of this attack operation was inevitable. Great as the success of early operation is, one must acknowledge that there *is* danger in a serious operation like laparotomy, done for *any* purpose, and if one could *choose* the time for such an operation, one would certainly choose a time after the subsidence of an acute inflammation, when preliminary treatment could be adopted, and special and deliberate precautions could be taken against disaster. There *are* very numerous cases of mild appendicitis which do *not* need operation, and I emphasize this statement because I wish to protest against the disingenuous attempts to earn a reputation for conservatism which have been often made by those who refer vaguely to others as performing "indiscriminate laparotomies for appendicitis," "operating upon every case," "cutting every one open for colic," etc.

Such statements are untrue, and do harm by lulling into a false sense of security the man who for the first time meets with a treacherous case.

What led, in the case whose history has been just read, to the diagnosis of "perforative appendicitis, with suppuration already begun," was, in the first place, the *sudden* severe pain felt, toward the end of the second day, in the right iliac fossa, followed in a few hours by a rapid rise of temperature, and the existence of a palpable, sensitive tumor of recent formation. The combination of these two signs, in my experience, invariably means suppurative disease. Now it is true that in this case the appendix lay at the most favorable situation, at the extreme right, was next to the anterior abdominal wall, and the pus was well restrained from spreading by a complete abscess wall. If it is asked, Why operate upon such a case immediately? I reply, Why not? If a patient is in good condition, if an operation is certain to be demanded sooner or later, why wait for the abscess to reach a large size, and expose the patient all the time to *some* danger of rupture, with general peritonitis, or general sepsis, or extensive burrowing of pus? Such delay means conservatism of pus, to be sure, but has no advantage, and yet so distinguished an author as Mr. Treves, who speaks so slightingly of American operators, tells us that "surgical interference before the fifth day should not be undertaken except in the presence of very emphatic symptoms." I dislike much to wait for the symptoms of a serious malady to become too instructively emphatic.

Case II.—Henry B——, a healthy young man, aged twenty-four, had, in July last, an attack of severe abdominal pain, which, however, lasted only one night, and its nature was not determined. He remained in good health from this time up to November 29th. On this date he was suddenly seized with severe abdominal pain, which was felt most intensely in the right iliac fossa, and which was accompanied by nausea and vomiting. The pain continued the next day, but nevertheless the patient attended to his work, that of a baker, every day for the next eight. He then went to bed, the pain abated somewhat, though marked tenderness in the right iliac fossa continued. He was admitted to the Roosevelt Hospital on the night of December 11th, twelve days from the beginning of his illness, able to walk perfectly well, though looking worn and ill. His temperature was 100.5° F., and his pulse 90. Rigidity of the abdominal muscles was not well defined; the belly was quite flat, but marked tenderness existed at the typical situation, two inches from the anterior spine of the ilium toward the umbilicus. On deep palpation a small tumor could be indistinctly felt. The diagnosis was "deep-seated small abscess of some duration, due to appendicitis."

Operation was done the next day, December 12th, at my clinic. An incision about four and one-half inches long was made about one inch outside of the linea semilunaris. The peritoneal cavity was deliberately opened throughout three and one-half inches, and no adhesions or any other inflammatory products were at first seen. The base of the appendix was found by carefully examining the caput coli, and the appendix was traced from this point backward, inward and upward, behind the caput coli, to a small inflammatory tumor. The end disappeared in this tumor. The base of the appendix was first ligated with two ligatures and divided between them, and the two cut ends were disinfected with the cautery. The appendix was then separated, by dividing its mesentery, until the tumor was reached. The intestines were carefully pro-



tected with sponges, the tumor broken into, and about one-half ounce of pus was evacuated. The abscess cavity lay quite behind and to the inner side of the caput coli. No connection existed. The abscess cavity was carefully sponged out without irrigation, and the whole cavity packed with iodoform gauze out to the external wound. On the next day the temperature, morning and evening, was normal, and the chart shows the subsequent history. Dressings were made on the 16th, 19th, 22d, 24th, and so on, until January 4th, when secondary sutures were applied to hasten the healing of a flat, granulating surface. Union was complete on January 9th, and the patient was allowed to be up and about on January 12th, thirty-one days after operation. He has remained well since.

The story of this patient is a not very uncommon one, the disease beginning in the usual manner, developing very slowly, then coming almost to a standstill, perhaps because the abscess lay so well protected behind and to the inside of the caput coli. Very likely if he had been treated in bed from the beginning, the temporary cessation of symptoms, so often called cure without operation, might have been more complete, and a period of imperfect health without marked signs of disease might have followed, this period ending in an outbreak of disease more or less severe, and possibly fatal. In some similar cases, of which I have seen several examples, the collection of pus becomes completely encysted—that is, surrounded by a very thick inflammatory wall, and the patient attends to his usual avocations, though always partially disabled. These cases, when they do come to operation at a late period, are very difficult to cure, for though it is easy to open the abscess, the dense, almost cartilaginous wall, is very unfavorable to granulation healing. The diagnosis in the case whose history has just been read was based upon the history of the outbreak, the persistence of symptoms, the ill look of the patient, the existence of fever, and the presence of tumor.

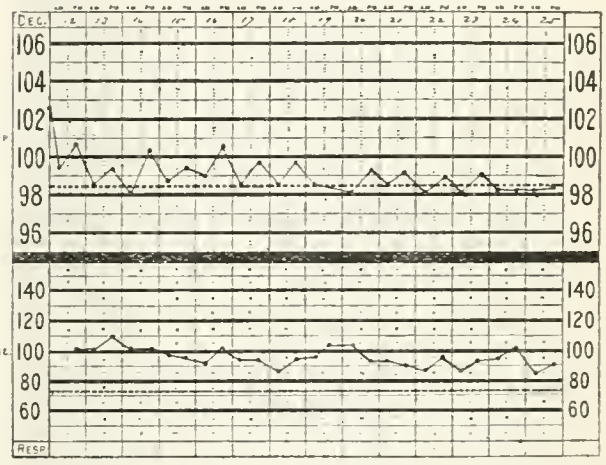
Neither the use of the exploring syringe nor an inves-

tigation of the rectum, which latter method some of my colleagues seem to think highly of, were needed to convince any careful observer that disease existed for which there was in reality only one remedy. Mr. Treves tells us, when writing of the suppurative cases, that "the later the operation is delayed, the more easily and directly can the pus be reached." This statement is a pleasing one to those who continue to believe that the pus in these abscesses always makes its way toward the anterior abdominal wall near Poupart's ligament. It can hardly be true of those cases, and they are common enough, in which the pus burrows in exactly the opposite direction, nor does it take any account of the damage that is being done, both general and local, while the "ease" of the operation is so gratifyingly increased. The same author also states that "if a very early incision became the rule, it would frequently happen that the matter could not be reached without first opening the general peritoneal cavity, and could not escape without first finding its way into that space." This statement is perfectly true, but I fear that many practitioners share with Mr. Treves the erroneous belief that, because it is true, we should delay interference, in the hope that some easier method may turn up. Now I wish to call especial attention to the fact that has been developed almost entirely by American surgeons, that the safe way to open these deep-seated abscesses is to first deliberately open the peritoneal cavity and carefully note the relations of the parts. It is then a comparatively simple matter to cautiously unravel the tangled mass of organs—that is, it is much simpler and safer than to cut steadily onward from the blind side, and before one knows what the wall of the abscess is made up of. Then, before such a deep-seated abscess is actually opened, if the road that has been cleared to it is lined with carefully held sponges, a small opening can be made into the abscess and the pus caught on a sponge almost guttatim and harmlessly removed. This practice has been a common and successful one in New York for a considerable time. Cases of deep-seated abscess opened at an early period in this manner will very rarely, indeed, end in any other way than in rapid recovery. Numerous cases are occurring where delay in operation allows of the commencement of a sepsis for which the knife is a poor remedy. Nevertheless, cases will be met with, as in the aged or the very fat, or the already overdistended, in which the chance of the abscess approaching the surface is to be preferred to the danger in such cases of a long or very difficult operation.

Case III.—A. H——, a sturdy German girl, aged twenty-three, had frequently had acute attacks of abdominal pain, the exact nature of these being unknown. On Wednesday, December 9th, very severe general abdominal pain was felt. This pain was continuous, and remained general until eleven o'clock on Thursday morning, when it quite suddenly became localized in the right iliac fossa. Great tenderness on pressure in this region was noted, and nausea and vomiting began and persisted throughout the day and the following night. This patient was admitted to the Roosevelt Hospital on the night of December 10th last, pain and tenderness having diminished, and the temperature and pulse being respectively 100. The signs already described were noted, and also that the point of maximum tenderness to pressure was situated two inches to the inside of the anterior spine of the ilium and a small fraction of an inch below the line drawn to the umbilicus. Slight rigidity of the right abdominal muscles was present. Constipation had existed since the beginning of the attack. No signs of other illness than appendicitis could be found. It seemed not improbable that the attack might subside, and operation was not suggested. On the following day, while the general pain was nearly gone, the local tenderness was the same, and the temperature had risen to 101° F.

The general appearance of the patient was excellent, and, had the local tenderness diminished, I should, on the morning of December 12th, have thought that the patient was recovering, for the temperature had fallen to 99.4° F. But though no tumor existed the local signs were clearly those of a sharp, inflammatory process, and were not subsiding. Operation was, therefore, done on December 12th. Incision was made as in the preceding case, and the peritoneal cavity deliberately opened. On first searching for the appendix it could not be found, and search was then made for the caput coli. This also was absent from the neighborhood of the wound, though the large intestine, which proved afterward to be a transverse colon, constantly forced itself into the wound. Finally, after systematic examination over a wide area, the appendix and caput coli were found far back in the right loin, near the kidney, and quite firmly adherent at this point. The distal half of the appendix was entirely gangrenous, perforated, and surrounded by a couple of drachms of pus. A few imperfect uniting adhesions existed at the inner side, and on the outside the appendix was firmly attached to the lateral abdominal wall. The appendix was separated with ligatures from its mesentery, ligated at its base with catgut, and cut away, the stump being as usual disinfected with the cautery. After thorough dry-sponging, the cavity, where diseased tissue had existed, was packed with dry iodoform gauze, without tube drainage, and a general bichloride dressing applied. No shock occurred, and the next morning and evening temperatures were, respectively, 98.4° F. and 90.4° F.

The chart tells the story of the subsequent course in



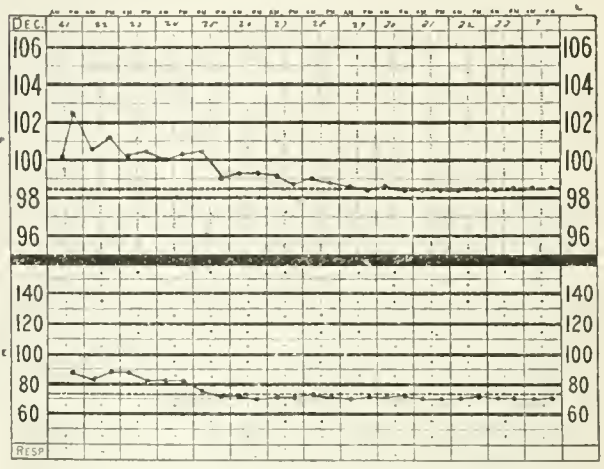
this case. Dressings were made every fourth day until December 25th, when secondary sutures were applied to close a nearly flat, granulating surface. Union was complete on December 31st, and the patient was discharged on January 16th.

This case is suggestive of a not uncommon incident, occurring not long after the beginning of an attack, and which sometimes gives rise to a false feeling of security. I refer to the fact that at the beginning of the third day the temperature, which had been 101° F. twelve hours before, had fallen to 98.4° F. Probably the rise is due to the invasion of an absorbing surface of septic material, and the fall to coagulation in the vessels, and the temporary stay of absorption. At any rate, it is a phenomenon which has frequently occurred, even in severe cases, and it proves that the temperature alone is not a safe guide as to the severity of the lesion. This case also demonstrates the value of a diagnostic feature to which I called attention more than two years ago. I refer to the fact that in the early stages of appendicitis the most acute tenderness is felt at a point, quite accurately, two inches from the anterior spine of the ilium, in the direction of the umbilicus. If the examination is made with one finger-tip alone, not with three or four, this characteristic will rarely fail of demonstration. The point of greatest tenderness is sometimes a little removed from the spot described, but the variations are rare, and not great. Of the truth of the observation I have been as-

sured by many friends who have themselves tested it frequently. The sign is not invariable, but nearly so. One would hardly look for it, as some seem to have done, in the advanced stages of the disease, when abscess is approaching the rectum. In difficult cases, and some of them are very difficult, and no two are quite alike, the discovery of the appendix, even that of the caput coli, may baffle for a while a careful search. I believe the better plan is to first insert the finger, which will often detect the appendix at once. If that method is not immediately successful then one should look for the caput coli, for if this is found, the base of the appendix is of course to be detected. If doubt still exists, then one should follow the ascending colon downward till the caput coli is reached and the point where the ilium joins it seen. Systematic search will always be rewarded. Recent adhesions will always yield to the finger-point or some other dull instrument, while old ones can frequently be more safely cut. If one keep close to the wall of the appendix such cutting can be made safe, though sometimes it is best to leave a thin scale of the wall on an intestine, and occasionally it may be unwise to insist on the full dissection of the organ. Even then, if the wound is treated by wide packing cure will result by granulation.

Case IV.—L. T. G——, a gentleman aged fifty-six, of heavy build and usually excellent health, while on his way to New York from a distant city, was quite suddenly seized, at nine o'clock in the evening, with nausea, vomiting, and general abdominal pain. His illness was so severe that, before reaching New York, he telegraphed to Dr. Henry F. Walker, of this city, to meet him on arrival. He was carefully taken in an ambulance to his hotel, reaching there on the morning of December 21st last. He looked ill, and complained of severe abdominal pain, felt chiefly in the anterior part of the right loin. He was put to bed, and visited frequently during the day by Dr. Walker, who strongly suspected acute appendicitis. His temperature remained at 100° F. until evening, his pain increased, and his general look of serious illness became steadily more marked. At nine o'clock that night, forty-eight hours from the beginning of the attack, I visited Mr. G—— at the request of Dr. Walker. The patient had the gray, tired look so characteristic of commencing sepsis. His abdomen was moderately distended, rigidity of the right abdominal muscles was highly developed, and very great tenderness on pressure was noted at a point considerably above the usual situation and over an area of several inches at the front of the loin, but at no other part of the abdomen.

The temperature had risen within two hours from 100° F. to 102.5° F., and the pulse was full and bounding. The diagnosis made was that of acute gangrene of the appendix, with perforation. I believed, and stated, that operation should be done without delay, if a rapidly fatal condition was to be anticipated. Dr. Walker was entirely of the same opinion, and we were reinforced by that of Dr. Weir, who was called in consultation. Operation was done at midnight, in the presence of Drs. Walker, Weir, Geo. M. Swift, and C. T. Parker, the latter gentleman immediately assisting me. A very large incision was required, high up in the loin, on account of the great thickness of the abdominal wall. The appendix was found lying to the outside of the ascending colon, well in the loin. It was curved like the letter S, was five inches in length, and as large round as a man's thumb, owing to a very extreme degree of over-distension. It was completely gangrenous from apex almost to the base, but not perforated. This condition rendered its separation without rupture very difficult, but this was finally accomplished, the exudation being very slight, and it was ligatured close to the colon and removed. The stump was immediately cauterized. On further examination the appendix was found to be stuffed to the utmost point of tension with soft fæces, a very unusual condition. No pus had formed, so that the region formerly occupied by the dead organ was completely cleared of diseased tissue. The large cavity was treated, as in the other cases, by dry-sponging, and then was packed with iodoform gauze, without tube drainage. No nausea or other unfavorable sign followed the operation. At eight o'clock the next morning the temperature was 100.3° F., and at 10 P.M., 100.1° F. Comfortable days and nights followed, as is



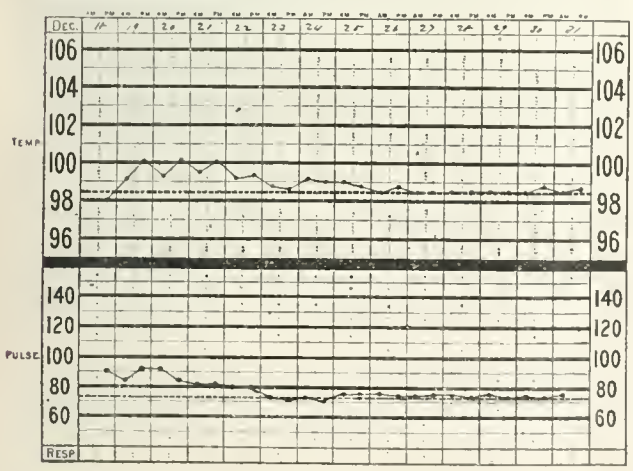
shown by the chart, the bowels acting after the second day with enema or mild laxative. The first dressing was made on the 25th, and other dressings followed every fourth day. On February 2d the patient was able to walk about the city freely, with a small line of surface granulation only unhealed.

This case represents very well a not uncommon class, in which gangrene of the appendix develops rapidly, septic signs appear early, and the diagnosis not having been made, decisive action often follows, rather than precedes, septic paresis of the gut and general septic peritonitis. And yet the indications were not more clear than is often the case when the lesion is by no means so grave. Fortunately Dr. Walker appreciated at an early period the fact that for this particular case of disease but one remedy was worth considering, and having reached that conclusion he lost no time in applying the remedy. The circumstances were not agreeable. The patient had come to New York on a flying trip, intending to return home in twenty-four hours. No member of his family was with him, and both Dr. Walker and I were perfect strangers. Fortunately he was a man of courage and a brief explanation was sufficient. While Dr. Weir was being sent for, all preparations were made for a careful operation, and as soon as possible, at midnight, it was done. No one present failed to appreciate that the lesion discovered was such as would have within a very few hours passed beyond either medical or surgical control. If this were an isolated case, we might be excused for failing to learn the special lesson it teaches. But it is by no means an isolated case, as can be well attested by those who have had the opportunity to see many desperate cases that have been dallied with until the opportunity to save life has passed. Is it any satisfaction at such times to comfortably say that some very bad cases have gotten well without operation? Are morning and evening consultations in order for several days after the diagnosis has been made, and the fact appreciated that there is really only one proper remedy? It is a noticeable fact that cases operated upon after long delay and numerous consultations are frequently fatal or extremely hazardous. It is of no comfort to be assured that few cases die before the fifth day, for we know positively that those who die on the fifth day have begun to die on the second or third, and if we would avert such an end we must anticipate the beginning of conditions which, with or without medicine or surgery, have but one end. I am surprised to see in the printed report of the "Proceedings of the County Medical Society of Philadelphia," at a meeting

held in September last, that so representative a man as Dr. Pepper said that "if every case of appendicitis were operated upon the mortality would be tenfold what it now is." The mortality is at present over twenty per cent. in cases treated by the expectant plan, so it is very evident that Dr. Pepper's view of the possibilities of surgery is a very black one But it is hardly worth while to follow his line of argument, for it seems to be based on the assumption that surgeons wish to operate upon every case of appendicitis. I have never read or heard that any surgeon has expressed such a wish. My own experience, and that of many others, has been that operations for acute appendicitis done at the right time, and before the disease has progressed too far, is nearly invariably successful. Out of some fifty such cases I have seen only one die. I should like to adopt the clever suggestion made some time ago by Dr. Jacobi, that we cease to talk of "early" operation, and make use of the term "timely" operation. This expresses exactly what should be done. So soon as the conclusion has been reached in a given case that operation is the proper remedy, the operation should be done then, if no contra-indication exists. Of course, if a diagnosis cannot be made, delay is unavoidable, but when the decision has been arrived at the operation should be done, whether in the evening, or at midnight, or in the early morning. If one has the courage of conviction as to the remedy, he will not delay long.

As regards the diagnosis of the conditions which should lead to operation, I must differ entirely with Dr. Pepper and others, who think highly of the method of examining the appendix through the rectum. In the early stages of appendicitis this method has no value whatever. Of course, those who are accustomed to allow abscesses to reach a large size, will in time find a bulging tumor low down in the pelvis. We had better devote our attention to learning the signs of suppurative appendicitis before the abscess has threatened the rectum.

Case V.—On December 15th last, I was requested by Dr. Isaac Adler to see with him Arthur B——, a pale, delicate-looking boy, aged fourteen. In August last the lad was in Paris with his parents, where he had a quite severe attack of illness, characterized by very great right iliac pain, vomiting, fever, and very obstinate constipation. He was attended at this time by Dr. Herbert, an English physician, and by Dr. William M. Polk, of this city, who pronounced the case one of appendicitis. The



boy spent eighteen days in bed, and then was considered well. On the voyage back to this country a mild attack of abdominal pain occurred, and on November 4th, here in New York, he had a well-defined attack of appendicitis in which he was attended by Dr. Adler. This attack occupied in all a little less than three weeks. On December 5th a fresh attack again occurred under Dr. Adler's observation, occupying about one week. In the intervals between the attacks referred to the boy was only partially well, being pale, not vigorous, thin, and irregular in appetite. When examined by me, on December 15th, he looked old and tired, and was clearly not well. Physical examination developed only one clear sign of disease—namely, decided tenderness on deep pressure with a single finger at the typical situation of the base of the appendix. But the history of the case, and more especially the accurate observations made in the last attack by Dr. Adler, left no room for doubt that we had to deal with a true case of recurrent appendicitis. Early operation was decided upon, as much safer than the closest passive observation, and the operation was done on December 18th, in the presence of Dr. Adler, and with the immediate assistance of Dr. C. T. Parker. The base of the appendix was readily found, and this portion and the adjacent peritoneal surfaces were in a normal condition. The appendix pointed straight downward and inward, and was firmly attached by its apex to a point deep in the pelvis, more than four inches from the abdominal wound, where it ended in a small inflammatory tumor. The separation of the appendix at this point was difficult, owing to its depth and to the very close attachment of small intestine, but slow dissection finally opened a small abscess containing not more than half a drachm of pus, which was caught on a small sponge. The tip of the appendix was quite destroyed, and a small scale of its wall was left attached to the small intestine, lest removal of it might open the gut. The base of the appendix had been first severed after ligature and the stump cauterized. A long strip of packing was carried to the seat of the abscess, and the outer wound more freely packed, though about half of it was closed by suture. The usual outer dressing was then applied. During the next twelve hours occasional vomiting occurred, but the morning and evening temperatures on the next day were 99.2° F. and 99.3° F. For two days accumulations of gas in the intestines were troublesome, but yielded to enemata. The chart tells the story of a very unbroken convalescence, and the patient left his bed on the thirty-second day, with a piece of adhesive plaster to support the edges of the closed wound. At this time he had a perfectly healthy color, was bright and happy, and had gained much in flesh. He has continued perfectly well since that time.

This is a typical though not severe case of what has been called recurrent or relapsing appendicitis, a form of the disease which is being constantly more and more clearly recognized; that is, through the more frequent appreciation of the true nature of first attacks, and through the more careful study of the patients' subsequent histories, we have learned that while many mild cases of appendicitis tend toward recovery, and some severe ones, too, many of these are prone to relapse, some in a mild way, over and over again, until finally a severe, or even fatal attack appears, and some having a very severe attack on the second occasion. Many of these cases get over an attack and are pronounced well, but they are not well, and they do not feel so. Tumor and local pain disappear, though the latter can often be discovered if careful examination is made. But the patient is not really restored to health. He loses flesh, becomes anæmic, is often ailing, sometimes quite disabled by dull pain in the right side, and the bowels are frequently constipated. After a longer or shorter period he has another sudden outbreak of appendicitis and again gets "well," as it is called, and then has another outbreak. Others really appear to get well, and forget completely the former illness, when they, too, are surprised by a violent repetition. Many of my medical and surgical friends have assured me that they consider the tendency to relapse, after apparent recovery without abscess or operation, as strong, although far from invariable. This is my own opinion, and yet I fully believe that in numerous cases the disease cures itself by obliteration of the calibre of the appendix. I would ask those who speak so confidently of the permanent recoveries from severe attacks of appendicitis how long and how completely their patients have re-

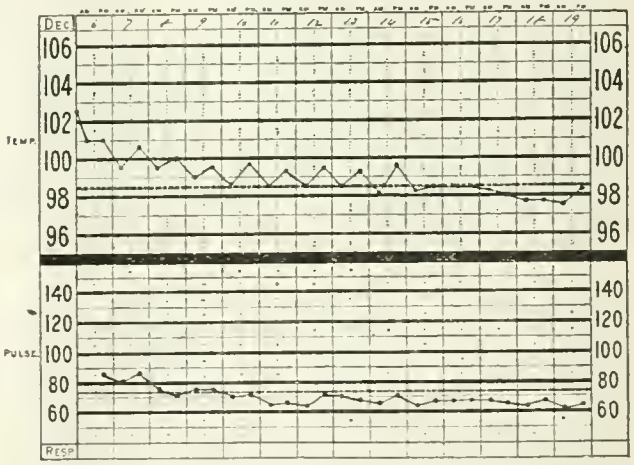
mained well. I would also ask them how much time their relapsing patients have lost, and how much illness and anxiety has been suffered in the course of a half dozen attacks. These points must be taken into consideration, as well as the actual danger in any one attack. One of my patients had twelve attacks in one year, and during that time was never well, and in all, three months were spent in bed. Operation restored permanent health completely. Another, a physician in the country, for several years had attack after attack, on different occasions, spent weeks in bed, and was on the point of giving up his practice and going to live in a city where, if necessary, he could obtain surgical help, when I persuaded him to have his appendix removed, which was done successfully.

In many of these cases we have reason to feel fairly safe as regards the probable danger to life from the next attack to be anticipated, for in many of them a long antecedent history aids much in the prognosis. But even in these cases we feel anxious, and in those whose attacks are increasing in variety we cannot but feel that they are in constant danger. A voyage, a journey, a pleasure trip, has over and over again been selected by the disease to make its reappearance. In those again where the effects of old attacks are noted in the form of more or less clearly defined tumors at the site of the appendix, or where imperfect health occupies the interval between attacks, the desirability of surgical interference has been clearly demonstrated. Of course no general rule can be laid down which will apply to all cases. Each one deserves study by itself, and by comparison with others. Owing to the repeated attacks of inflammation and the existence of firm adhesions, the operation in recurrent cases may be quite difficult, and is accompanied by some danger, as is every surgical operation of importance. I have myself operated on such cases some sixteen or seventeen times. I lost one patient from sepsis, a danger which cannot as yet be absolutely excluded from any surgical operation. All of my other cases have remained permanently well without recurrence.

Case VI.—Nearly a year ago I was asked by Dr. Charles Hackley to see Dr. W——, a physician, fifty-six years of age, a personal friend of many of those here tonight. I found him in bed complaining of rather obstinate constipation, but without fever or other noticeable sign of illness In the right loin, at a point corresponding to about the middle of the ascending colon, or a little lower, could be felt a small tumor, an inch and a half in length and an inch in width, partly movable and very slightly tender on firm pressure. While this felt somewhat like a lump of fæces in the colon, I feared it was a carcinoma of the gut, and rather expected increasing obstruction. Laxatives, however, emptied the bowels, and the tumor disappeared. At the end of five or six days the patient was up and about, with but little of the former sensation in the loin left. But his discomfort in that region was never entirely absent, the bowels were irregular in action, and occasionally mild abdominal pain was a source of annoyance. On Friday, December 4th last, in the afternoon, he felt more pain than usual and went to bed early, remaining in bed the next day, decidedly more uncomfortable, and the pain being clearly referred to the right loin. At about two o'clock very severe agonizing pain set in and continued uninterruptedly until, at half-past five, he was visited by Dr. Charles T. Poore, who administered morphine, giving marked relief.

At Dr. Poore's visit, at 5.30, the temperature was noted to be 100° F. I saw the patient at seven o'clock and found him complaining of constant pain, which was rendered totally unbearable by the lightest touch over a point two inches above the usual situation of the base of the appendix. The pain on pressure was great, though diminishing, as one drew the finger upward and outward in the loin. In this short time, one hour and a half, the temperature had risen to 102.5° F., and the pulse was that of severe disturbance, and very weak. The patient was pale and anxious-looking, and his general appearance was that of one suffering from marked shock. I saw him again in three hours, and found the conditions the same, with the signs of shock still prominent. The diagnosis of acute appendicitis with perforation was made, but I did not dare to administer an anæsthetic, for I believed the patient would succumb from that alone. It was determined to treat him for shock during the night, in the hope of bringing him to an operable condition. Fortunately this was accomplished, and when I visited him the next morning, with Dr. Charles Hackley, his general condition had very greatly improved, the temperature had fallen to 101° F., and the pulse was much better at 86, though the local signs remained perfectly clear.

Operation was done at twelve o'clock, in the presence of Drs. Charles T. Poore, Charles Hackley, F. W. Murray, and C. T. Parker. These gentlemen assisted me at the operation. An incision rather high in the front of the loin was made, and the peritoneal cavity deliberately opened. The appendix was readily found lying to the outside of the ascending colon, pointing upward and reaching nearly to the kidney. It occupied the exact situation of the tumor felt eight months before. The organ was about three inches long, was very much thickened and inflamed throughout, and had about it a drachm or more of free pus. No protecting abscess-wall existed, and at the middle of the appendix was a round hole the size of a pea, and a corresponding fecal concretion lay near by, free in the peritoneal cavity. The removal of the appendix was easily effected, the stump treated in the usual manner with the cautery, the cavity cleansed by dry sponging and then fully packed with iodoform gauze without tube drainage. The wound was partially closed at the upper end by suture. The temperature the next morning was 99.6° F., and in the evening 100.6° F., the general condition being perfect. The chart shows a very



normal convalescence. The wound was dressed on the 10th, 15th, 16th, 19th, and so on until the 27th, when secondary sutures were applied to hasten the closure of the nearly flat, granulating wound. The patient was allowed out of bed on the thirty second day, and has since remained perfectly well.

The case of Dr. W——, just reported, suggests, in the first place, that mild attacks of appendicitis from which patients often rapidly recover may be followed by relapses of dangerous severity. So far as I am informed, no surgeon has ever proposed that, to provide for such cases, every mild attack of appendicitis should be treated by operation. This insinuation has been made by Dr. Pepper and others, and, starting with a statement which has no justification in fact, an argument has been raised which does not follow the lines of thoughtful study. The fact that dangerous relapses may follow mild attacks would rather suggest that every case of appendicitis is well worthy of careful study, not only at the time of the mild attack, but for a very considerable length of time

subsequently. In this manner we shall sharpen our diagnostic faculties, and so, probably, learn to more accurately forecast the future than at present we are able to do. R. W——'s history also calls to mind that, even in a severe attack of perforation by concretion, contra-indication to immediate operation may exist. In this case the contra-indication present was a very marked degree of shock which followed immediately upon perforation, and resembled that following bullet-wounds. I should have been unwilling to administer an anæsthetic to any patient presenting the appearance which R. W—— did for many hours after perforation occurred. His subsequent history justified the delay, for with the aid of a moderate quantity of morphine, stimulation, and rest, his shock disappeared, and on the following day he was in a condition to bear the rather long and difficult operation required, without the slightest injury. The case of the late Dr. Agnew resembled that of R. W— , in that marked shock, too great to permit of operation, immediately followed perforation. Dr. Agnew never rallied, and it was only as a desperate resource that Dr. Sands felt forced to operate at the end of two days' delay.

The feebleness of old age, unusual obesity, complicating diseases, and unmanageable over-distention, may justify the surgeon in refusing to offer with the aid of the knife the relief perhaps most urgently called for. Probably the most conservative practitioner, knowing the lesion which existed in R. W——'s case, would not advise, under similar circumstances, the trusting of his patient's life to any medical measure known to science. The extraordinarily great variety in the signs and lesions of the disease under discussion will probably prevent us from ever formulating a set of rules such as some writers delight in referring to as routine practice. It will, however, always be good routine practice to study critically every individual case of a disease which belongs to a class that often enough destroys life, and to be willing to carefully weigh the value of experience even if contributed by those who observe from a different standpoint.

Let us remember that it is not so very long ago, quite within the clear recollection of many of us, that we were taught that idiopathic peritonitis was a common enough disease, and that peritonitis in general was to be treated by medical measures only. Since then we have added to our store of knowledge, first by one observer and then by another, much valuable information in regard to the causes of peritonitis, and the possibility of attacking these successfully. The surgeons, and chiefly those of America, deserve the credit of having added most largely to our knowledge of appendicitis, the most frequent of all causes of peritonitis in the male. To them chiefly belongs the credit of having demonstrated the practicability and safety of treating this disease by the incomparable method of removing its cause. If we would accomplish the most by our discussions on this topic, then physicians and surgeons must join hands, the physicians accepting the fact that the surgeon does not always wish to operate, and the surgeon gladly stepping aside when he sees that success can be attained by his colleague's gentler methods.

Five years ago we stood a little timidly on the edge of the new country, determined to go on; but dreading the discovery of hidden dangers, perhaps of insuperable difficulties. To-day I do not hesitate to say that never in the history of surgery has a major operation so soon established itself in so strong a position, so well supported by sound knowledge and unimpeachable facts as the timely operation for appendicitis.

Temperance Movement in Japan.—Mr. S. Tsuda has presented a petition, signed by more than three thousand members of the Temperance Society of Japan, to the Japanese House of Representatives, praying for increased taxation of alcoholic liquors, with the object of lessening the consumption of them.

LEGISLATION ON MEDICAL AND HEALTH MATTERS IN THE VARIOUS STATES IN 1891.

By HENRY A. RILEY, A.B., LL.B.,

NEW YORK.

(Continued from p. 317)

Maine, Massachusetts, Michigan, Minnesota, Missouri, Montana, and Nebraska.—The Maine Legislature passed a law modelled after the New York statute of 1890, relative to the prevention of blindness in new-born children. It provided that should one or both of the eyes of an infant become inflamed or reddened at any time within four weeks after birth it shall be the duty of the midwife, nurse, or person having charge of said infant to report the condition of the eyes at once to some legally qualified practitioner of medicine of the town or neighborhood where the parents reside.

A failure to comply with the law was punishable by a fine not to exceed $100, or by imprisonment not to exceed six months, or both.

A law was enacted providing for the State registry of vital statistics, and the Secretary of the Board of Health was made Registrar.

Blanks were required to be issued to clergymen, physicians, sextons, town clerks, and other officers, in order to secure a record with full particulars of all births, marriages, and deaths. All births and marriages were required to be reported within six days.

No burial or disinterment was allowed without a permit, and this was to be furnished by the clerk of the town after the physician and undertaker had filed certificates setting forth the facts connected with the death. When this occurred without medical attendance the facts could be stated by relatives or other persons.

Any person wilfully neglecting or refusing to perform any duty imposed by the law was to be fined not more than $100 for each offence.

The rule in this State allowing only $5,000 for a death caused by negligence was adopted, and it was also required that the action for damages should be brought within two years.

A general law regulating dentistry was passed, and all persons practising without a certificate after the expiration of three months were to be fined in a sum not less than $25 and not more than $100.

A State Board of Examiners was appointed consisting of five dentists in good standing and who had been in practice for five years.

All persons besides dentists in practice at the passage of the act, and who had secured certificates within three months, were required to pass an examination in anatomy, physiology, pathology, therapeutics, chemistry, and the theory and practice of dentistry.

The fee for this examination was $20, which was not to be returned if the candidate was unsuccessful, but he was entitled to a second examination without further charge.

The law stated that its provisions did not apply to physicians and surgeons in the discharge of their professional duties, nor to any citizen in the extraction of teeth in cases of emergency. A law was passed providing that no cemetery should be nearer than twenty-five rods to any dwelling house if written protest by the owner was made.

It was made the duty of all teachers of the public schools to devote at least ten minutes a week to teaching the children the principles of kindness to birds and animals.

The offence of wilfully driving any nail or spike into a log which would be likely to cause injury to the saw or endanger the life or person of anyone engaged in handling the log was declared to be a serious one, and the punishment was made a fine of from $100 to $500, and imprisonment for a period of from one to five years.

The offender was also liable civilly to double the damages sustained.

The Eastern Maine General Hospital at Bangor was incorporated and given authority to establish a training-school for nurses.

The Gardiner Hospital at Gardiner was also incorporated, and similar authority given for a training-school.

The Maine Homœopathic Hospital at Portland was established under the management of thirteen trustees.

Massachusetts.—In Massachusetts a considerable amount of legislation was enacted which will be of interest to the profession. It was provided that physicians should report at once in writing over their own signatures to the Selectmen or Board of Health all cases of small-pox, diphtheria, scarlet fever, or any other disease dangerous to public health which they had been called on to attend. The penalty was a fine of from $50 to $200.

An amendment was passed to the law authorizing the taking of dead bodies for anatomical purposes, so as to include among the institutions which could furnish such bodies the workhouse or public institutions of the city of Boston.

It had been formerly the rule to permit the giving up of bodies which were not claimed for twenty-four hours, but this limit was extended by amendment to three days.

A law was passed that any inmate of penal or charitable institutions who shall have syphilis shall be at once placed under proper medical treatment, and where the attending physician thinks the treatment requires, or the disease is contagious so as to be dangerous to the health and safety of the other prisoners, the patient shall be isolated until the danger of contagion has passed.

If any prisoner at the expiration of his sentence has syphilis so as to be considered dangerous to public health or safety, such prisoner shall be detained and properly treated until the danger of contagion has passed away. The expenses of support of prisoner are not to be more than $3.50 per week.

Any person receiving an infant for board or procuring it for adoption must use diligence to ascertain if the infant is illegitimate, and if he believes so, must notify the State Board of Lunacy and Charity, and the Board may remove such infant if deemed necessary to preserve its life.

The manufacture and sale of children's toys containing, or coated wholly or in part with, arsenic is prohibited under a penalty not to exceed $100. The State Board of Health was authorized to investigate in order to ascertain the existence of arsenic in any paper, fabric, or article offered for sale, and $1,000 was appropriated for xpenses. All vendors of suspected articles were required to furnish samples for analysis when payment was offered, under penalty of $100.

The statutes against oleomargarine, which seem so elaborate in many of the States and yet apparently so little obeyed, were added to by a strict enactment which prohibited the manufacture or sale of any imitation of genuine butter except under such conditions as would inform the purchaser of the real character of the article. The penalty for disobedience was a fine varying from $100 to $500, or imprisonment not to exceed one year.

All packages of oleomargarine or butterine must be plainly marked with letters an inch long and a placard must be conspicuously posted in the store stating "Oleomargarine sold here."

All pedlers were required to have wagons marked, "Licensed to sell oleomargarine."

Hotels, restaurants, and lunch-counters were required to have placards informing their guests that oleomargarine was used.

Three members of the State Board of Agriculture were organized as a Dairy Bureau and the special enforcement of the law was given to it.

The warfare against the gypsy moth was continued, and the State Board of Agriculture was ordered to provide and carry into execution all reasonable measures for the extermination of the pest. The zeal of the crusade was evinced by an appropriation of $50,000 to make it effective.

The State Board of Agriculture was also authorized to investigate the best method of protecting persons against the dangers arising from the presence of tuberculosis in the food-products of cattle, and $2,500 was appropriated for this purpose.

The sweating system of making ready-made clothing was the subject of a vigorous enactment, and the inspectors of district police were directed to examine the tenement-houses where such garments were made, and the garments themselves, to see if they were cleanly and free from vermin and every matter of an infectious or contagious nature. If evidence of infectious disease was found the State Board of Health was to be at once notified and such action taken as the circumstances required.

Goods made in other States under similar unhealthy conditions and shipped to Massachusetts were to be examined.

The following appropriations for permanent improvements in public institutions were made: For enlarging the State Lunatic Asylum at Northampton, $30,000; for new male insane asylum at the Tewksbury Almshouse, $10,000; for the Massachusetts Homœopathic Hospital at Boston, for the erection and furnishing of new buildings, $60,000.

Michigan.—In Michigan a statute regulating dentistry was enacted which amends in a number of particulars the previous statute. Section 1 of the old law was amended so as to make it unlawful for anyone to practise unless he shall have received a diploma from a college with a course of instruction and practice fully equal or equivalent to that of the College of Dental Surgery of the University of Michigan. Students were allowed to assist in dental offices and in the College of Dental Surgery of the University, under the immediate supervision of the legal proprietors and the professors, but they could not assume charge of an office. Those persons now in practice who are not registered are directed to furnish the facts of graduation, etc., by affidavit, and all persons found qualified will receive certificates on payment of $3. The fee for a regular examination for registration in other cases was fixed at $10.

An act was passed permitting the organization of corporations for the acquisition and dissemination of knowledge pertaining to veterinary medicine and surgery, and for the elevation of the standing of professional education, and the association of members of the veterinary profession for mutual recognition, advancement, and fellowship. Any nine persons in actual practice who have received the degree of Doctor of Veterinary Medicine and Surgery from any medical school or college can become incorporators. The qualifications for membership consist of a reputable practice in Michigan as a veterinarian for two years, with at least one year's study in the office of a veterinarian, or one college year in a reputable veterinary college, and a compliance with the rules of the association.

The term for which such corporations can exist is thirty years, and they are entitled to hold property to the extent of $10,000.

No person affected with small-pox, diphtheria, or scarlet fever was allowed to enter any public place or conveyance, or in any way subject another person to danger of contracting disease. The same prohibition was made against the exposure of any child or irresponsible person suffering from contagious disease.

The penalty for a violation was a fine from $25 to $1,000, or imprisonment from twenty to ninety days.

The use of oleomargarine or butterine in any public institution was prohibited, and any warden, superintendent, or official who should knowingly violate the law was liable to a fine of $100 and costs, or imprisonment for ninety days, or both.

The Central Board of Control of State Institutions was established, and to it was given the charge of the State

Public School at Coldwater, the Michigan School for the Blind at Lansing, and the Michigan School for the Deaf at Flint. The Board was to consist of four members and the Governor *ex officio*.

The following appropriations for improvements were made: To the Eastern Michigan Asylum at Pontiac, $25,000, for the purchase of fifty acres of land and the erection of a cottage; to the Michigan Asylum for Insane Criminals, $25,000 for the erection and furnishing of a building for seventy-five male patients.

Minnesota.—In this State a law was passed regulating the practice of midwifery. All persons hereafter beginning practice, if graduates in midwifery, must present their diplomas to the State Medical Examining Board. If found genuine, a license for one year was to be issued on payment of $1.

If the applicant is not a graduate the Board must have an examination, for which a fee of $2 is to be paid.

Persons now in practice must present proof of such fact to the State Board and be registered. The State Board can revoke or refuse licenses for unprofessional or dishonorable conduct, or for neglect to make proper return to the health authorities about births. The law does not apply to physicians or surgeons, or to students of medicine, or to gratuitous services in cases of emergency.

The penalty for practising without a license is a fine of from $10 to $50, or imprisonment for a period from ten to thirty days.

Quite an elaborate law in regard to the use of oleomargarine was enacted. All imitations of butter were obliged to be colored a bright pink, and all articles manufactured or sold as substitutes for lard were to be branded in heavy letters, "Lard Substitute," and the names of the ingredients given. Hotels using the substitute must print on the bills of fare, "This food is prepared with lard substitute," or "adulterated lard," and if no bills of fare are provided, a card giving the information must be conspicuously posted. The Dairy Commissioner was directed to enforce the law, and was given authority to enter all places of business, factories, etc.

Violations of the law were declared to be misdemeanors, with a fine not to exceed $100, and imprisonment not to exceed ninety days.

The Pharmacy Law was amended in a number of particulars. To entitle a person to be registered he must be twenty-one years of age, and be graduate in pharmacy or medicine, or else have had four years' practical experience and have sustained a satisfactory examination before the State Board of Pharmacy, or be a registered assistant at the time of the passage of the act.

An assistant must be at least eighteen years of age and have had two years' experience. The fees for certificates are $2, and for examinations $5.

The penalty for compounding drugs, or allowing it to be done, without a license, is $50; but the law does not interfere with the regular practice of a physician, or with the making and vending of proprietary medicines, or with the sale by general retail dealers of alum, blue vitriol, borax, castor-oil, epsom salts, licorice, logwood, saltpetre, water of ammonia, and Paris green labelled "Poison." The penalty for not affixing the "poison" label to dangerous drugs is $5.

The law of 1889 relative to the sale of poisons was amended to read as follows: "Provided that the provisions of this section shall not apply when the sale is made upon the written prescription or order of some practising physician."

The charters of a number of cities contained provisions for the appointment of a city physician who should furnish medical and surgical attendance to such poor as he may be required to attend by the proper authorities. Health officers were also provided for.

The following appropriations were made for permanent improvements and for buildings, etc.: St. Peter's Hospital for Insane, $12,500; Fergus Falls Hospital for Insane, $138,000; Minnesota Institution for Defectives, $75,000; Rochester Hospital for Insane, $30,000; Minneapolis City Hospital, $25,000.

Missouri.—In this State there was little legislation of interest to the profession.

The duties of veterinary protection were transferred from the State Agricultural College to the State Board of Agriculture, and the salary of the State Veterinary Surgeon was placed at $2,500.

A law was passed forbidding the sale or giving away of the carcasses of swine, sheep, cattle, etc., dying of contagious diseases, and the owners must bury, burn, or remove them to a place remote from public roads.

Any person editing, publishing, or disseminating any newspaper, magazine, etc., principally devoted to scandals, lechery, intrigues, etc., is guilty of a felony and may be punished by imprisonment not to exceed five years.

A good law for the safety and health of employees was passed, and all cities of five thousand inhabitants and upward were directed to appoint inspectors to examine all factories employing over ten persons.

It was provided that no minor or woman should clean gearing or machinery in motion, that hatchways should be protected, fire-escapes furnished, doors be made to open outward, and that seats should be furnished in factories and mercantile establishments for females when not obliged to be on their feet.

The inspectors were given authority to order changes made in thirty days if anything was found to be unhealthy.

An appropriation was made of $18,000 for new buildings at the Lunatic Asylum at Fulton, and of $15,000 for a hospital building at the St. Joseph Lunatic Asylum.

Montana.—The bad plan of farming out the insane was adopted in this State, and a Board of Commissioners appointed to carry it into effect. The Board was to consist of the Governor, Secretary of State, and Attorney-General. It was directed that there should be advertisements inserted in six papers for proposals for the custody, maintenance, and treatment of the insane. The successful bidder was to give a bond for $50,000, and the contract was not to be longer than three years. The contract was to require a secure and suitable building for the safe-keeping, care, and treatment of insane persons, and the management was to be according to rules adopted by the Board.

A State Board of Pardons was established, consisting of the Secretary of State, the Attorney-General, and the State Auditor. Its duties were to consider any communications received from the Governor stating that he had granted a pardon absolute or conditional, or had remitted a fine or forfeiture. Upon receipt of any such communication the Board was to publish notice of a public hearing, at which those in favor of, or opposed to, the granting of the pardon could be heard. Within twenty days after the hearing a decision was to be given and communicated to the Governor.

A law was passed making it unlawful to sell or give to any child under sixteen years of age any lewd picture, book, paper, etc. It was also declared unlawful to exhibit any such picture or book in presence of a child. The offence was made a misdemeanor, with a fine not to exceed $300, or imprisonment not to exceed six months, or both.

An appropriation of $80,000 was made for the care, custody, maintenance, and treatment of the insane; one of $7,000 for the education and transportation of deaf-mutes, feeble minded and blind children, and of $4,000 for the salary, office, and travelling expenses of the State Veterinary Surgeon.

Nebraska.—Nebraska was one of the few States enacting new and elaborate statutes regulating the practice of medicine. A State Board of Health was established, consisting of the Governor, Attorney-General, and Superintendent of Public Instruction, with four Secretaries, two from the Allopathic School, one from the Homœopathic, and one from the Eclectic.

It was declared to be unlawful to practise without a

certificate, and no certificate could be issued to a person who was not a graduate of a legally chartered medical school or college in good standing, which qualifications were to be determined by the Board.

Another section defined the term "medical school or college in good standing" as follows: "A medical school or college requiring a preliminary examination for admission to its course of study, and which requires as requisite for the granting of the degree of M.D. attendance on at least three courses of lectures of six months each, no two of said courses to be held within one year, and having a full faculty of professors in all the different branches of medical education, to wit, anatomy, physiology, chemistry, toxicology, pathology, hygiene, materia medica, therapeutics, obstetrics, gynecology, principles and practice of medicine and surgery, and clinical instruction in the last two named." It was provided, however, that the three-year clause did not apply to diplomas granted before July, 1891.

If, on examination of the diploma, it was found to be regular and to qualify the holder, as above stated, a certificate was to be issued, which was required to be filed in the office of the county clerk of the county where the practitioner resided.

Physicians in practice at the time of the passage of the act were required to present them within six months, and if genuine a certificate must be issued.

Certificates could be refused to persons guilty of unprofessional or dishonorable conduct, and could be revoked.

No person could recover in any court any sum of money for professional services unless he has complied with the provisions of the law.

Any unqualified person who shall engage in the practice of medicine, surgery, or obstetrics is guilty of a misdemeanor, and can be fined in a sum not less than $50, and not more than $300, together with costs.

Any person shall be regarded as practising medicine, within the meaning of the act, who shall profess to heal or prescribe for, or otherwise treat, any physical or mental ailment of another. But nothing was to be considered as prohibiting gratuitous services in cases of emergency, and the law does not apply to commissioned surgeons in the United States Army or Navy, nor to nurses in their legitimate occupation, nor to the administration of ordinary household remedies.

Any itinerant vendors of drugs, nostrums, ointment, etc., were guilty of a misdemeanor, and could be fined $100, or imprisoned for three months, or punished in both ways.

A law was passed authorizing municipal corporations situated on streams liable to overflow from natural causes, or obstructed by dams, to include the land within three miles of the city limits in a sanitary district, and organize a Board of Trustees with power to supervise the drainage.

An appropriation of $25,000 was made for the erection of buildings for the Nebraska Institution for Feebleminded Youth, near Beatrice, and one of $75,000 for the erection and furnishing of two wings to the Hospital for the Incurable Insane at Hastings.

(To be continued.)

A Cruel Fling at the Medical Profession.—There are fifty-four errors in the Latin of an Eldridge Street quack's diploma, and the only wonder is how the regular physicians were able to detect them.—*Evening Sun.*

Cholera Among Sharks.—An Indian journal states that an epidemic of cholera broke out a short time ago among the sharks which infest the Indian Ocean. The bodies of seventeen British seamen, who had died of cholera in the harbor of Bombay, on the hospital ship, were sewn up in weighted canvas bags, taken out to sea, and cast overboard. It is believed that the sharks feasted upon the remains of the dead seamen, and thus became infected.

RACIAL IMMUNITY AND INOCULATION, AND SECULAR RESTRICTION OF CERTAIN DISEASES TO PARTICULAR LOCALITIES BEFORE COMMERCE DISSEMINATED THEM.[1]

By ALBERT S. ASHMEAD, M.D.,

NEW YORK.

The subject of racial immunity and inoculation, and my attempt to transfer the immunity of the Japanese from scarlet fever to the Caucasian, has been honored by the interest of Professor Stillé. In a letter to me the professor suggests an explanation of the absence of the disease from Japan, which seems to me, in spite of a theory in which I still believe, very worthy of consideration. "Japan," says he, "has until very recently been segregated from other countries, and a similar segregation appears to be the reason why the eruptive diseases of Arabia and the farther Orient were unknown in Greece and Rome, and indeed in nearly all of Europe, until the time of the Crusades. Measles and scarlet fever were often confounded, but neither appeared in Europe until the period above mentioned."

"The subject," he says further, "is interesting. The secular restriction of certain diseases to particular localities before commerce disseminated them, may be largely illustrated, besides the instances I mentioned, by syphilis, tubercular leprosy, and cholera."

The subject seems to me to be of such importance for Japan that I shall bring to some extent before the medical profession of that country, through the *Sei-I-Kwai*, the exchange of ideas which has taken place between that eminent authority and myself. I give, therefore, a letter which I wrote to Professor Stillé, and his reply to it:

(Copy.)

"DEAR PROFESSOR STILLÉ: Your suggestion as to the secular restriction of certain diseases to particular localities before commerce disseminated them, and the instances you gave, namely, syphilis, leprosy, and cholera, as well as the disease which occupies us at this moment, has opened to me a large field of reflection and work. You have in your last letter compared Japanese immunity from scarlet fever to the immunity of Europe from the same disease before communication with the Orient. I have thought that this order of ideas might be applied to the three other diseases I have mentioned above. There are certainly in their Japanese history phenomena which militate powerfully in favor of your theory, if it is a theory. Syphilis is said to have been introduced into that country in the seventh century, from India, along with Buddhism. Since that time the race seems to have acquired gradually a remarkable power of resistance, due evidently to a secular series of inoculations. The mildness of the type it shows there has always been since the Dutch invasion, that is for three centuries, an object of surprise for the foreigners. Inoculated into the European it breaks out under the most virulent form which the disease can take. It appears, then, that the four centuries during which the scourge has been known in Europe could not do the same work of attenuation which was performed by thirteen syphilitic centuries in Japan.

"As to leprosy, I have strong reasons for believing that it was brought to Japan even before Buddhism. The Japanese bore a prominent part as a nation in the wars of the Indian princes in the Malay peninsula; this brought them in contact with the Arabs, who had gained a foothold in China before the sixth century. They went in their company to India and Africa, and thus leprosy, I have no doubt, voyaged to their shores, as in an opposite direction it had travelled to Europe. Here, of course, the fact is not to be left out of sight that the Japanese are a negritoid race, and, therefore, peculiarly susceptible of leprous infection.

"I come now to cholera. There never were more than six epidemics of cholera in Japan: the first in 1822,

[1] Communicated to the Sei-I-Kwai.

the last in 1890. According to the latest reports of the Sanitary Bureau, published in the *Sei I-Kwai* (*Medical Journal*), February, 1891, each and every one of these epidemics was imported by European ships. You see that in this disease, as well as in the others, the analogy holds good.

"I now return to our subject, scarlet fever. In Hirsch,[1] to whom you have referred me, I found a fact which is contradictory to those I have just mentioned in relation to Japan. 'As to the native habitats of scarlet fever, we can only affirm that the endemic area of scarlet fever is a limited one, that at many parts of the globe the disease has never occurred except when imported, that it has been able, indeed, to exist in those countries for a longer or shorter period, but has died out in the end; and if it has reappeared, it has always been necessary to assume a fresh introduction of the morbid poison. The reason why the continents of Asia and Africa have remained hitherto almost free from the sickness, *notwithstanding many importations of it* (italics are mine), does not admit of being explained.'

"I find that Quatrefages, Pruner Bey, and others, while they are on my side with a vengeance, in one respect, differ much from my views in another. Negritoid-Polynesian races are not susceptible of scarlet fever, according to these writers. On the other hand, the same authorities set their faces against any admission of racial pathology. Dr. Drysdale (*British Medical Journal*) states positively that scarlet fever will not flourish in Hindostan, and that it has always died out speedily when isolation was used. I say that neither will it flourish in Japan, and there also would entirely disappear if isolation was made use of. Why, the race was in contact with the Arabs and with India as far back as the sixth century. If Europe caught it from the farther Orient, why have not they taken it? Even more than this: the high nobility of Japan is a white Indonesian race, the result of a crossing of the 'farther Orient' white blood with a negritoid-Malay element. This fusion took place in the most natural manner. During their long intercourse with the Arab civilization they fell, as a matter of course, more or less under the influence of the Islam, and must, for a long time, have sat at the feet of the learned Mohammedan doctors. For the Islam had, at that time, not only a power due to its arms, but an immense prestige due to its arts and sciences, which has hardly been equalled to this day.

"That the disease cannot originate in Japan, but must of necessity, if it appears there at all, be introduced from the outside, is the opinon of the same Hirsch. For, says he, 'the well-founded presumption of the organic nature of the virus of scarlet fever excludes the idea of an autochthonous pathogenesis; the disease never arises but in consequence of a conveyance of the specific poison, and the spread of the sickness is dependent on the fact that the virus, reproduced in the sick person, and eliminated by him, forms new foci of infection."

"Even admitting that the few cases of scarlet fever which are on record in Japan are the first signs of a pathologic revolution similar to that which occurred in Europe in the middle ages, there is one thing which deprives this alarming portent of much of its sinister significance. It is this: all observers without exception, for instance, Takaki, Baelz, and others, declare that there is in the Japanese a peculiar resisting power to scarlet infection. This must be of great comfort to such Japanese as may have felt a little alarmed during the latter times; the consciousness of their powers of resistance will at least take the sting out of their fears.

"Yours very sincerely,

"ALBERT S. ASHMEAD.

"TO PROFESSOR ALFRED STILLÉ, M.D., LL.D.,

Emeritus Professor of Theory and Practice of Medicine, University of Pennsylvania."

[1] Geographical and Historical Treatise, Sydenham Society Edition, London.

(Reply.)

"DEAR DOCTOR ASHMEAD: . . . . The subject that interests you just now was one that always interested me during my active professional life, especially as a teacher of the Theory and Practice of Medicine. The difficulties that environ it are very many and great. Without going into detail, I will only refer to one. There was a time when the contagiousness of scarlet fever was generally denied. Professor Chapman, who held the Chair of Practice in the University of Pennsylvania when I was a student of medicine (1833–36), affirmed positively that it was not contagious; and for years afterward the matter remained undecided. There were many who affirmed it to be so slight a disease that they had never met with a fatal case of it. It is plain, therefore, that one cannot reach an absolute conclusion, in regard to this and similar questions, without he embraces in his survey a very wide field both in time and space.

"The greater or less immunity of different races to particular diseases is hardly susceptible of explanation, and as little is the mortality they suffer from them. The deadly effects of cholera and small-pox and syphilis in our aborigines are well known, and I remember the fearful ravages of measles among the colored troops during our Civil War. You know, also, that syphilis, when first introduced, was epidemic, and ravaged every rank from the dunghill to the palace, and yet it has now become both attenuated and restricted. Tubercular leprosy has a nearly analogous history.

. . . . . .

"Thanking you, etc., I remain,

"Very sincerely yours,

"ALFRED STILLÉ.

"TO DR. ALBERT S. ASHMEAD."

It appears thus that the disease (scarlet fever) travelled from Arabia and the farther Orient to Europe after the Crusades, and that in America, as late as 1836, its contagiousness was absolutely denied; it had appeared in this continent about the year 1735.[1] Dr. Nott, in his essay on "Variability in the Types of Disease,"[2] in speaking of scarlet fever in America, says: "Scarlet fever is an imported and acclimatized disease. Small-pox, scarlet fever, and other imported diseases have preserved among us the same character and habits they brought from Asia, like many of their animals, plants, and even insects.

"Small-pox was unknown in Europe for many centuries after the Christian era, though common in China long before. Scarlet fever is of still later date, in Europe, and was so rare in the United States that *Dr. Rush, about the beginning of the present century, makes the remark that no physician here would be likely to see it more than once in a lifetime.*" (Italics are mine.)

This same disease, in which the profession would scarcely believe at the beginning of the present century, is now endemic in every large town of this country, and visits the smaller places in the form of epidemics. It attacks with impartiality every fraction of the Caucasian race, and spares almost entirely the Ethiopian. The latter seems to be protected by the nature of his skin. Professor Tucker, in an article entitled "Influence of Race upon the Type and Treatment of Disease,"[3] comparing the Negro and the Caucasian, says: "The depuratory action of the skin is increased in the negro; perspir tion is greater and different in properties in the negro. Caucasians removing from temperate to warm latitudes have their function of skin first stimulated, then the liver, bowels, kidneys, and lungs; hence liver diseases, diarrhœas, and dysenteries result. In negroes removing from a tropical to a temperate zone, the same organs suffer, because their skin does not perform its function. Black absorbs more heat, while white reflects. The negro ab-

[3] Savannah Medical Journal, 1861.

sorbs more heat, hence increase of skin action. In the acclimation of Europeans in India diseases of the internal organs are common. If they survive these attacks they become acclimatized, but it is at the expense of their fair complexion, for they assume a darker hue of skin and entirely lose all trace of their Caucasian color. The skin is the main physiological difference between the white and the negro. Residence in the South will not effectually protect the subject against yellow fever, nor are even those who have been born there fully protected. This seems to be a disease pre-eminently opposed to the white race. Every change of residence may require a fresh acclimation."

He quotes Dr. S. H. Dickson's letter to Dr. Nott: "The Anglo-Saxon race can never become acclimated against the impress of periodical or malarious fevers. An attack of yellow fever acclimates him so far as it is concerned, but does not in other respects against malarious influences. It is my full belief that negroes become insusceptible of the impression of the cause of periodical, or what we call malarious, fever."

We have, then, here, a race similarly situated as to scarlet fever with the Japanese, and the immunity seems to be founded in the race itself; that is, in one of its peculiarities, the nature of the skin. Now, it is my opinion that the Japanese also, from the same cause, enjoy their exemption. It is well known, now that the customs of the Japanese are so generally discussed, that they have made a secular experiment upon their own skin, by their remarkable customs of hot bathing and hot-tea drinking; and should it be wondered at if their skin had acquired properties so pronounced in a certain direction as to become the basis of immunity from a disease against which another race is protected also by the nature of its skin?

Returning now to the general subject of immunity, I shall mention the opinion of Dr. Merrill.[1] This shows how general immunity may be obtained. "There is scarcely room for doubt that perfect immunity against the recurrence of small-pox, and the vaccine disease, may be secured by certain repetitions of either; and it may well be doubted whether these are the only forms of disease of which this fact can be affirmed." "Immunity from measles, scarlatina, whooping-cough, and mumps, is also supposed by many to be secured by single attacks of these diseases, but observation scarcely justifies this doctrine." He speaks of repeated attacks of malarious fevers granting a measure of immunity, and questions "whether the same may not follow attacks of cholera in India." He cites the principle of "partial immunity as illustrated also by the destructive epidemics which prevailed in the middle ages, when twenty million lives are said to have been lost in Europe by black death, and in the single year 1499, thirty thousand people fell victims to the sweating sickness in London. These and other fatal diseases not now known to us prevailed many times in succession, as yellow fever and cholera do in modern times; the lives preserved gained gradually a partial immunity from subsequent attacks, as in our fevers of the present time."

On the question of individual immunity Dr. D. Francis Condie[2] speaks of persons who always escape unhealthy influences, or who may handle poison vine (Rhus Radicans) with impunity. He mentions further, from his note book, persons in which primary vaccination was performed with pure, recent, active matter; but without the operation being followed by any other result than a slight soreness at the part where the virus was introduced, and which was entirely gone in a day or two. The same thing occurred after a second and a third insertion of vaccine matter that had been used successfully in other cases; finally, inoculation with variolous matter was resorted to, and with the same negative result. In three of the cases the patients, after the lapse of six, eight, and fourteen years respectively, were exposed to variolous infection during severe epidemics of small pox, and all contracted the disease, but in a mild and greatly modified form. So that he argues that "individual immunity resulting from vaccination varies."

One of the most striking instances of racial immunity is that of the Jews. They owe it to their lasting allegiance to the sanitary code of their first legislator, and it is well known how purely their descent has been preserved.

French observers say that the life of the Jew in France is in advance by twenty years of that of the Christians. Dr. Marsh,[1] in contrasting the purity of the Jewish descent from Abraham, with the Gentiles or Christians from Christ and His followers, who were also Jews but who varied their inheritance by inter-marriage with other races, claims that "the Jews have proved themselves of the purest and finest type of the Caucasian race." In referring to circumcision as a factor in this continuance of purity, he says that the Turks, Copts, and Ethiopians, and all other Christian nations inhabiting Egypt, universally practise it. It is enforced by the Koran, not only on the burly, lusty boy, but equally alike on the most delicate and tender maiden. Regular professionals, who perform the operation, traverse the streets and place themselves in prominent places, and loudly vociferate in Coptic or Arabian language, "Who wants to be cut?" Circumcision as a sanitary and religious rite, with its correlative hygienic, dietetic, and therapeutic accompaniments, frequent ablutions, purifications, abstinence from hog meat and other unclean things, were in practice by the ancient Egyptians, and formed the most prominent part of a fundamental religion far back in the confines and first development of the germ of their ancient civilization, and when the ancestors of the Abrahamics were wandering nomads in Mesopotamia, on the other side of the river Euphrates. It never became a Hebrew institution until friendly relations had been established between Abraham and the Egyptians. Then it was initiated by the circumcision of Abraham and Isaac by the express command of God. In ancient Egypt, religion and medicine were blended in the same profession, its rules and practices enforced by an order of priests, to whose dictum not only the most abject slave, the lowest peasant, but the highest potentate—Pharaoh himself—must bow, even to his daily bill of fare; its programme regularly furnished by his priest and physician, from which he dare not deviate. Circumcision was introduced among the ancient Egyptians as a sacred rite of the gravest import.

Moses himself was an Egyptian priest, educated in all the deep research and arts of the Chaldean Magi and mystic philosophic development of Egyptian and Oriental science, and all that was then known of the science of medicine in its general principles, and its application of details for the preservation of health and prevention of disease.

He concludes: "Statistics and well-established authority concede that Jews enjoy a wonderful immunity not only from consumption but a large portion of diseases that assail the health and life of the human race."

A racial immunity not inferior to that of the Jews has been observed in the pure-blooded black race. They outnumber the white in centenarians. The statistics of the United States census of 1830 show that the chances of attaining this great longevity were forty times as great with the free colored as with the white, and with the slaves eleven times as great. In 1840 the disproportion was somewhat diminished, as there were nine centenarians among the slaves and thirty among the freemen to one white. "This greater number of the colored race at the age of a hundred," says Dr. Forry,[2] "is attributable to a mere tenacity of life, which seems unsusceptible of explanation."

[2] New York Journal of Medicine, 1884.

In the "Report on the Sanitary Condition of the Laboring Population of Great Britain" we read: "Some constitutions are found to resist vaccine matter. Here and there constitutions appear which resist all the noxious influences by which they are surrounded and attain extreme old age. Not infrequently we find the existence of these solitary individuals referred to as proofs of the general salubrity of the very circumstances under which generations have fallen and been buried around them. The greatest proportion of centenarians are of the laboring classes; and instances have appeared amidst the crowded populations in some of the worst neighborhoods of London where the average duration of life is the lowest." "All writers," says Dr. Forry, "note the extraordinary fact that centenarians are generally, if not universally, found in that class of society which gives the lowest mean duration of life."

It is evident that we have here people surviving in spite of the most unfavorable circumstances, and we naturally conclude from this that they have been preserved by a special immunity belonging to their race.

Wherever there is a change in the action of a disease, a corresponding change is observed in the subject himself; it is the latter that changes, not the disease. This has been noted by the illustrious Graves in his "Clinical Medicine." Sydenham, too, the greatest of modern physicians, and some of the master-minds of antiquity, refer to the same fact. Professor Alison of Edinburgh, also, in two clinical lectures on pleurisy and pneumonia, entered upon a consideration of the change of inflammatory diseases. Blood-letting, formerly employed with success in our treatment of disease, to-day will not do. The individual resistance is diminished.[1]

Shall we assume that through the bringing together of nations long isolated from each other, through the formation of new races, a new susceptibility is evolved? It would almost seem (though I am by no means prepared to assert the principle) that the simple mixture of two races may be productive of new pathologic tendencies. The Spaniards who established themselves in South America had never had yellow fever, and, to the best of our knowledge, the Indians with whom they mixed had never been visited by it either. The hybrids got it, as if the simple meeting of the two races had generated it like a spark.

Quatrefages remarks that a human race may be unacquainted with one or several diseases, or with certain morbid forms, though at the same time but too apt to contract them. Once attacked it may even develop this disease, which is new to it, in a more violent form than any hitherto known. He also says, however, that ethnological immunity does exist, mentioning elephantiasis in the Indies and Barbadoes, which attacks only natives, creoles, and individuals of mixed blood. Whites of European origin have, as yet, escaped. In Ceylon, too, the same disease attacks only the same classes of people. Hindoos and Europeans, strangers in the island, are exempt from it.

I have been led into these various discussions by the question of scarlet fever, and I wish now to wind up an exposition, which the reader may perhaps deem a little rambling, by an observation which strikes me as, if not practically important yet singularly interesting. While all other diseases seem to become exhausted as the centuries go on, this disease alone increases (in the Caucasian at least), and seems to become rampant with age. At its first appearance in a new field its very individuality as a disease is put in question; the diagnosis between it and measles is obscure; its contagiousness is doubted or denied. But the time always comes when it must be recognized as being undoubtedly infectious, and from only affecting adults it finally allows no exemption to children, excepting the new-born.

[1] An epidemic of influenza may simply mean a general occurrence in the same place of a condition of non-resistance to climatic factors, and not at all the presence of germs

From my study on the subject, and my attempted inoculations of a Japanese with scarlet-fever germs, I have arrived at the following conclusions:

1. The Japanese have now a relative immunity from scarlet fever.

2. Their race is peculiarly protected by the mixture of the races which have formed the nation.

3. Scarlet fever may introduce itself by intermarriage with susceptible blood. New foci of infection will be found in Caucasian half-breeds.

NOTE.—Perhaps the medical profession of Japan will be interested in the following passage, which I extract from Charles Anglada's "Étude sur les maladies éteintes et les maladies nouvelles"[1] (Paris, 1869). Such as are unacquainted with this excellent book I inform here that it contains a study of the plague of Athens; the Antonine plague; the plagues of the third and sixth centuries; variola; measles; scarlet fever; epidemic gangrene; the black plague of the fourteenth century; the sweating sickness of the fifteenth century; syphilis in the fifteenth century; and cholera in the nineteenth century:

"The historical study of scarlatina begins with a chronological puzzle. At what time has it begun to take its place among human diseases and complete that highly original group of eruptive fevers? We may choose between the two following solutions. Physicians generally do not seek beyond the sixteenth century the first descriptions relating to scarlatina. If we adopt this view, and if we take for granted that they took the disease at its very birth, its date would be a thousand years posterior to that of variola and measles (rougeole). Bateman[2] proposes another version, which, with certain restrictions, seems judicious enough. According to him the ancients knew these three fevers; but owing to the incompleteness of their indications many obscurities remained which were dispelled at the close of the sixth century by the Arabs. The latter demonstrated clearly the existence of these fevers, while still leaving in abeyance many questions as to their individual natures. Their successors, being the too servile slaves of their teachings, continued during more than a thousand years to confound these three diseases into one, of which they were only varieties. Their state of error was protracted to the end of the seventeenth century, and it was only then that more careful observations showed the distinctive characters and independent origins of these exanthems.

"It goes without saying that I leave to Bateman the whole responsibility of his personal belief in the antiquity of these fevers; but I may indorse his opinion without contradicting my own views as to their co existence as far back as the sixth century. The contemporary apparition of variola and rougeole represents the first symptom of an unaccustomed epidemic constitution, resulting from a concourse of influences unknown as to their nature, but revealed in their effects. The soil was thus prepared for receiving scarlatina, and it may readily be believed that it soon thrived in it. Have I not, in rambling through the writings of the Arabs, met with certain cutaneous efflorescences which seemed by exclusion to be akin to scarlatina itself? It would thus seem that this disease was at that time suspected, seen as through a haze, vaguely delineated. But if we take into account the confusion from which the differential diagnostic of variola and rougeole has with so much difficulty been extricated, we can fully understand how this indecision could have contributed in prolonging indefinitely the incognito of scarlatina, lost, as it were, among the morbillous exanthems. It was only by the dint of numberless observations, which represent the experience of several centuries, that it received at last its nosological baptism. It is by no means proven that it did not at an early period co operate in the epidemics, which were, at the origin, exclusively attributed to variola and rougeole.

[1] Reference kindly furnished me by Professor Stillé.
[2] Abrégé prat. des Malad. de la Peau, Trad. 1820, p. 102.

"Hufeland,[1] no doubt, had lost sight of these precedents, which he ought at least to have taken into account when he asserted that 'Scarlatina is a new disease which began to be observed only in the seventeenth century.' Whichever view may be favored, I am myself deeply convinced that there was not really between the simultaneous apparition of variola and rougeole and the later adjunction of scarlatina that interval of centuries which must be supposed to separate the two events, if we consider only and uncritically the dates set down by the historians of these diseases."

4 King Street.

FIBROUS MAMMARY TUMORS.

By CHARLES N. DOWD, M.D.,

ASSISTANT SURGEON AT THE NEW YORK CANCER HOSPITAL.

The practical questions which have to be decided concerning tumors of the breast are certainly very puzzling and of great importance. On the one hand there is the danger of allowing malignant tumors to grow beyond control; on the other, there is the possibility of doing needless operations and thus subjecting the patient to unnecessary suffering and discomfort. The tumors in which the connective tissue predominates are among the most perplexing ones—those known under the names: fibroma, fibroadenoma, fibrocystoma, or simply interstitial mastitis. These tumors are so common that most surgeons see many of them every year. The various forms which they take are well illustrated by the following six cases which have recently been treated at the New York Cancer, Roosevelt, and St. Luke's Hospitals, and at the Vanderbilt Clinic. For all but two of them I am indebted to Drs. McBurney, Hartley, and Curtis. The cases are selected because they serve as types. They are not especially uncommon, nor are they of statistical value:

Case I. *Diffuse Cystic Tumors.*—F. C——, a strong unmarried woman, aged thirty-seven, had noticed, four years before, a hard, pea-sized tumor in the margin of her left breast. It remained stationary for one year and then grew slowly. For the last few months it had grown rapidly, and when seen, July, 1890, a lobulated movable tumor occupied nearly the entire breast, with no involvement of surrounding tissues. It was painful on pressure and on movement of the arm. This was removed, and was found to be a fibrocystoma, composed almost entirely of small cysts. At the time of the operation the other breast seemed slightly indurated near its outer margin. Six weeks later this had increased until there were several nodules in the breast. Four months later, in January, 1891, there were more nodules, from the size of a hazelnut to that of a hen's egg. The breast was tender and enlarged, and there was a constant dull pain which at times ran up the arm. There was no adherence to the pectoral muscle and no axillary enlargement. The nipple was not retracted. On removal these were found to to be of the same character as those in the other breast. (See Figure III.)

Case II. *Circumscribed Fibrous Nodules.*—L. W——, a thin, pale, unmarried girl, aged nineteen. For five years a nodule had been growing in the left breast near the outer margin. It had grown from the size of a filbert to that of a pullet's egg. It was hard and freely movable, with no attachment to the underlying tissues nor to the skin, no retraction of the nipple, no axillary enlargement. It was slightly tender and occasionally painful during menstruation. When excised, May 21, 1891, it was found to have a rather indistinct capsule and to be a fibro adenoma. She again was seen January 5, of this year, and then had two similar tumors in the other breast, one the size of a pullet's egg, the other the size of a hickory nut. The first had appeared about July 1st, the other about December 1st. They were excised January 9th. Clinically and pathologically they were similar to the first one. (See Figure IV.)

[1] Manuel de Méd. prat., p. 463. 1838.

Case III. *Large Cystic Nodules, somewhat Circumscribed.*—E. O——, strong married woman, aged thirty-seven, who had borne a child one year and a half ago, and had nursed her. Four months before operation she began to suffer from pain in her right breast, which had been relieved by supporting it firmly. Both breasts had become hard and knotty, and in the upper inner quadrant of the right one there was a hard, movable tumor as large as a small hen's egg. There was no attachment to the skin, nipple, or underlying tissue. The axillary glands were slightly enlarged. On removal this proved to be a fibrocystoma with firm, fibrous tissue, one large cyst and several small ones, containing translucent fluid. She was seen eighteen months later and had indurated nodules in the breast.

Case IV. *Diffuse Fibrous Tumor with Calcareous Degeneration.*—M. H——, a fairly strong, hard working married woman, aged forty-three, who had noticed, two years before operation, a small, hard nodule in her right breast which had grown slowly and painlessly until the entire breast was involved. It was enlarged, hard and nodular, and from one of the nodules half an ounce of serous fluid was drawn. Four months previously she had discovered a nodule in the left breast, which had remained nearly stationary. The nipples and skin were normal. There were no axillary enlargements, nor was there any attachment to the pectoral muscles. On removal very small cysts were found in both breasts, much connective tissue and a few calcareous deposits. These tumors must have existed long before they were noticed by the patient.

Case V. *Diffuse Interstitial Mastitis, with a few very Small Cysts.*—M. T——, a fairly strong married woman, who had had children and normal lactations, the last one five years ago. Nothing abnormal was noticed in the breasts until one month ago, when she had discovered a small tumor in the right one. This had grown since then without marked pain or tenderness. There was no enlargement of the skin, nipples, or axillary lymph-nodes. When seen, the whole breast was enlarged, hard, and lobulated, and appeared cystic. The other breast showed similar changes, less marked. On removal there was induration through the entire breast with a few very small cysts.

Case VI. *Interstitial Mastitis with the Formation of a Small Abscess.*—M. M——, a healthy married woman, aged forty six. During her lactations, which had occurred several years before, she had had little milk and only slight enlargement of her breasts. She had never noticed any tumor, but two years ago had a temporary sense of discomfort in her left breast. August 17, 1891, she had a chill, and the next day her breast was hard and painful. This continued until November 5th, when it was excised. The breast then showed general induration, with a hard nodule back of the nipple about as large as a hen's egg, the overlying skin being inflamed and the axillary lymph nodes enlarged. After removal there was found interstitial mastitis with two small broken-down nodules just below the nipple, one of them a distinct abscess-cavity with necrotic walls.

These cases represent many phases of fibrous growth, from the small circumscribed nodule to the diffuse induration which involves the entire breast. The development of cysts, calcareous degeneration, and the softening and breaking down of the fibrous tissue were all present. Some of the tumors grew fast, some slowly. Yet on microscopical examination we find essentially the same features in all, the prime element being an increase in connective tissue. If we take the normal active and inactive mammæ as standards (see Figs. I. and II.), we notice to what extent this has taken place; the connective tissue increasing greatly—the epithelial elements diminishing in proportion, cysts developing in consequence of the pressure of the connective tissue on the ducts (see Figs. III. and IV.). Virchow[1] describes these changes in two stages: 1. The inflammatory stage, in which the

A, Acini. *D*, Ducts. *C T*, Connective Tissue *C W*, Cyst-Wall. *C*, Cysts. *V*, Blood-Vessels.

V.—CARCINOMA GROWING IN A FIBROUS MAMMARY TUMOR (Interstitial Mastitis).

The dilated ducts and the connective tissue indicate interstitial mastitis. In other parts of the tumor there are cysts similar to those in Plate III. The wildly growing epithelial cells *E* indicate carcinoma.

connective tissue is infiltrated with small round cells, and in which there may be a slight increase in the epithelial structures. 2. The stage in which these cells change, dense fibrous tissue forming, somewhat like that of a cicatrix. Hence there is shrinkage of tissue and pressure on the ducts and acini and consequent fatty degeneration of their epithelium, much of it becoming absorbed and the acini obliterated. In some cases cysts result from the obstruction of the ducts.

The most noticeable pathological difference in these specimens is that in some the cyst development has gone further than in others.

There was a marked tendency to progression in all. Both breasts had become involved in every case but one.

There are two questions which have to be decided regarding each tumor of this variety which is presented to us: 1. What is it? 2. If not removed, what will it become? As to the first, there are of course the ordinary rules: The benign tumors are likely to occur in younger persons than the malignant ones; they are more often multiple, involving both breasts and leaving the axilla free; painful at menstruation, and often containing cysts from which fluid may be aspirated. Still the difficulties of diagnosis are often very great. König [2] states that the diagnosis between fibroma, sarcoma, myxoma, and circumscribed interstitial mastitis is impossible.

These difficulties in diagnosis apply to all the forms of fibrous tumors. The diffuse ones often resemble scirrhus. The cystic ones are not to be distinguished from sarcoma or even carcinoma, as is illustrated by the following two cases which Erichsen [3] relates:

The first, a woman who had a cystic mammary tumor which had existed for twenty years but had an ulcerated surface. Six months later it had a purgating sarcomatous growth. The second, a patient, fifty-nine years of age, who had a hard tumor the size of a half orange which had existed five years, was freely movable and unconnected with the skin, giving no retraction of nipple and no lancinating pain; on the upper side several large cysts could be felt and seen through the skin. This was found to be a cystic scirrhus. Many features of both of these tumors suggested fibro-cystoma, yet it would have been a bad mistake to leave them alone.

The small circumscribed tumors would ordinarily be considered easier of diagnosis than the other forms. Yet they may be very puzzling. Take the first case here recorded—the one who came to the Vanderbilt Clinic in May with a small nodule in her breast. On what basis could we have stated that it was not sarcoma? We know that many tumors which exist for years as small circumscribed nodules either are sarcomata or afterward become such, *e.g.*, a small round-celled sarcoma of the neck which came into Dr. Hartley's service at the New York Cancer Hospital last September. The patient was thirty-eight years of age. When ten years of age he had noticed a hard, insensitive, pea-sized tumor in his neck just below his right submaxillary gland. This showed no change for fifteen years, when it became as large as a hickory-nut, but showed no other change for ten more years, when it began to grow rapidly. It was excised twice during the following three years, and when seen in September consisted of two lobes, each as large as a hen's egg. For twenty-five years this had been almost quiescent, a small and apparently harmless nodule, yet after that, it assumed such proportions as to threaten the patient's life. De Merinac [20] records a case where a hard, walnut-sized nodule, which followed a blow, remained stationary for fifteen years, and then in three months grew to the size of a double fist. It was removed and found to be a spindle-celled cystosarcoma.

Poulsen [4] collected the statistics of 33 cases of sarcoma of the breast which occurred in Copenhagen. Of the 33 ten had existed for five years or more and eleven others from one to three years. He states that several of these sarcomata had remained stationary for long periods. In one case, at the age of sixteen, a tumor, the size of a small walnut, had appeared inside the nipple after a blow. This showed no change for thirty-six years, excepting that it was slightly painful at menstruation. Four years after menstruation, however, it began to grow and was removed when it had reached the size of an orange. Thirty-six and four-tenths per cent. of those patients who recovered from the operation died from metastasis or recurrence. Schmidt [5] reported 15 cases of sarcoma of the breast from Professor Czerny's clinic, 8 of which had existed one and one-half years or more. Among them there was a myxosarcoma which for eighteen years had remained the size of a hazel-nut and then during two years had grown rapidly. Another had begun seven years previously as a small, movable nodule which had shown little tendency to grow but had increased slightly during lactations; during the six months previous to removal it had grown rapidly. Six of the 15 patients (forty per cent.) died from the effects of the sarcoma. The mortality, however, was in those patients in whom the tumor was recent and rapidly growing. We cannot state whether these tumors were sarcomata from the beginning or whether they began as fibromata. There is certainly a strong probability that some of them were sarcomata from the start.

This suggests the other question. Granted that a tumor is fibrous, may it later become malignant? *A priori* there are many things which would lead us to think that it may. A malignant tumor is caused by some influence which destroys the balance of growth, and causes certain elements to grow uncontrolled. This influence, whatever it is, acts especially where there is a disturbing factor, *e.g.*, cancer of the lip, tongue, and gum are often associated with the irritation of a pipe, or a carious or projecting tooth. Cancer of the breast and uterus frequently come with the atrophic changes which accompany the menopause. Now, a fibrous tumor is certainly a disturbing factor, and moreover, in the tumor itself we have a tendency to uncontrolled growth. If this tendency extends in the connective we may expect a sarcoma; if in the epithelium, a carcinoma.

When, however, we look for definite cases of these changes we are balked. When we cut a tumor out and examine it we can only tell what it is. We cannot tell what it would have been had it been left, nor yet what it was when it began. There are, however, many cases which throw light on this question, some where metastasis have occurred in such tumors, others where primary growths have apparently done so. There have recently been two cases in Dr. Hartley's division at the Cancer Hospital which bear on the subject. One where a wen was replaced by an epithelioma, the other where a uterine myoma was partly replaced by a sarcoma. The first, a woman aged sixty-seven, had had several wens in her scalp for ten years. In July, 1891, one of them became tender, and sharp, shooting pains were felt in it. It soon ulcerated and gave forth an offensive discharge. When seen in September this one was as large as a hen's egg, and was ulcerating, painful, and attached to the pericranium. There were six other ordinary wens on the head. On removal, the large one was found to be an epithelioma which had extended down to the periosteum. The others were ordinary wens, as shown by microscopic examination.

The second case was that of a woman who had had symptoms of a uterine myoma for twenty-five years. When she came to the hospital she was suffering from most profuse metrorrhagia, which was not relieved by any of the ordinary measures, and abdominal hysterectomy was performed. After removal of the uterus and its appendages the following condition was found. There was a large ovarian giant-celled sarcoma on the right side. In the uterus there was a large interstitial myoma there were also several small myomatous nodules just below the peritoneal coat. The interstitial myoma was broken down in the middle and extending from the endometrium

into this broken-down area there was much soft sarcomatous matter, similar to the ovarian sarcoma. The inference that the sarcoma had encroached upon the myoma is unavoidable. This, however, was a metastasis rather than an original growth.

Martin [6] states that among 205 corporeal myomata removed by operation, he found 4 encapsulated myomata becoming sarcomatous, 2 of which recurred and caused the death of the patients, respectively, seven weeks and four months after the operations. Doran [7] records the occurrence of a myoma, 2¾ pounds in weight, which was practically an expansion of the fundus of the uterus. In it there were two distinct kinds of cells which he figures: 1. Slender muscle-cells. 2. Shorter, thicker spindle-cells like those of a spindle-celled sarcoma. He considered these cells evidence of sarcoma, and his statement was accepted.

Dr. B. Farquhar Curtis,[8] of this city, records a case where an interstitial mastitis involved a breast and led to the development of cysts, the first nodule having been noticed four and a half months before the removal of the breast. In the mass there was a distinct carcinoma of small size which had apparently begun in the fibrous tissue near one of the cysts. (See Figure V.)

Billroth [16] figures a somewhat similar case, in which a carcinoma grew within an adeno-sarcoma, the tumor recurred as a circinoma.

Schmidt [17] records a cyst-sarcoma of the mamma which contained epithelial pearls.

Oldekop [9] records a case who had received a blow on the breast which caused a blood extravasation. After its resorption a hard nodule remained, which was stationary for fourteen years and then was changed into a carcinoma.

J. Hutchinson, Jr.,[10] records the case of a woman who from girlhood had a small round tumor just beneath the skin of the left breast. It was the size of a cherry, and did not grow larger until she was nearly forty-four years of age, when in two years it increased to a hard mass which was adherent to the skin and involved the axillary lymph-nodes. On microscopical examination this proved to be an adenoma imbedded in a scirrhous carcinoma.

Ponpiniel [11] records a case which is suggestive. A woman, aged fifty, had had a hard, painless, filbert-sized tumor in her left breast for twenty-one years. In March, 1887, an ovarian epithelioma was removed. Three months later the mammary nodule began to be painful, but grew steadily, and after another twelve months was removed and found to be an epithelioma. It recurred twice within two years.

Poulsen [4] records the case of a man who had a mammary carcinoma develop upon a nævus.

These cases indicate that either fibrous tumors sometimes grow into malignant ones, or that they form a favorable ground for the growth of malignant ones. They certainly show us that what are at one time clinically bland tumors, may at a later time be malignant ones, and this, from a practical standpoint, is what we have to consider.

The induration which remains after a puerperal mastitis resembles closely the fibrous tumors which we are considering. It would be of interest to know whether they have any etiological relation to carcinoma.

In the cases which Poulsen recorded there were 107 in which inquiry was made concerning previous mastitis. In twenty-eight per cent. of them it had existed.

Oldekop,[9] in 103 patients with carcinoma of the breast, who had borne children, found previous puerperal mastitis recorded in 36, or 34.9 per cent.

Schmidt [5] found a history of previous puerperal mastitis in 24 out of 109 patients who had carcinoma of the breast, and who had borne children.

Schulthess,[12] from studying over four hundred cases recorded by Billroth, Winiwarter, Fischer, Oldekop, Henry, estimates that about twenty-nine per cent. of those who had borne children had had puerperal mastitis.

Schroeder [5] estimated, from over one thousand puerperal cases, that mastitis was present in about six per cent. Hence, if over twenty-five per cent. of the mothers with mammary carcinoma have had puerperal mastitis, and only six per cent. of other mothers, it is fair to believe that the fibrous induration which remains in the breast after puerperal mastitis is an etiological factor in the production of cancer.

There is another argument which bears on the question. If pathologists and clinicians who have given very extended study to the subject believe that the transition from fibrous to malignant tumors occasionally occurs, we must give much weight to this opinion.

Birsch-Hirschfeld [13] states that a transition from fibroma into fibrosarcoma has occasionally been observed. König [2] states definitely the belief that interstitial mastitis changes sometimes into carcinoma, and fibroma into sarcoma which is prone to recurrence and metastases. Delafield and Prudden [14] state that fibromata by metaplasia partially change to form fibrosarcoma.

Klebs [15] states that fibrous mammary tumors are frequently the starting-point of cancer.

Billroth [18] indicates the belief that adeno-fibromata may be considered the early stages of cyst-sarcomata, and records two cases in which nodules which were long indolent later developed into cyst-sarcomata.

Gross [19] quotes Labbe and Coyne, and Duplay as being of the opinion that the metamorphosis of fibroma into sarcoma is so frequent that primary sarcoma of the mamma is rare.

Conclusions.—After reviewing the evidence, the following conclusions would seem to be warranted.

1. It is often impossible to distinguish fibrous mammary tumors from sarcomata or carcinomata.

2. The occurrence of metastatic growths in or about fibrous tumors; the sudden malignant growth of tumors which have existed for years as quiescent nodules, presumably fibrous; the change of wens into epitheliomata; the apparent change of uterine myomata into sarcomata; the apparent etiological relation between puerperal mastitis and cancer; the opinions expressed by high authorities—form a mass of evidence which would lead us to believe that fibrous mammary tumors may occasionally change to malignant ones. This change, however, is probably not very common.

[NOTE.—Owing to an engraver's error the titles of Figures III. and IV. are reversed. The two lines of description at the bottom of the plate-sheet apply to Figure V. only.]

Piperazine, the new uric acid solvent, can be employed externally, according to *Notes on New Remedies*, in one-per-cent. solution, applied to gouty joints by means of wet bandages. It may also be injected subcutaneously into the tophi, thus acting directly on the uric acid concretions. Outside the body uric acid gravel is readily dissolved in a one-per-cent. solution at blood-heat.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street

New York, April 16, 1892.

DEATHS FROM CHLOROFORM.

DURING the past month the daily press of this city has given publicity to at least two cases of death attributable, or attributed, to chloroform. One occurred during childbirth, and the coroner's autopsy showed a fatty heart.

The other took place in a man of some fifty years, who was being anæsthetized for a finger amputation.

It is not our purpose to discuss here the relative merits of the various anæsthetics, but to call attention to two recent propositions, which seem at once sensible and timely.

The first is an inquiry (*British Medical Journal*, note in *New York Medical Journal*) on a large scale which is to be made in the hospitals throughout Great Britain during the year 1892 regarding anæsthetics. "Eminent surgeons, anæsthetists, and general practitioners will contribute their clinical experiences, as supplemental to the conflicting results obtained by the experimental workers. The research will be made under the auspices of the British Medical Association. An influential and fairly constituted committee has charge of the plan of the inquiry, and record books have been prepared for the use of those who are willing to co-operate. These books have been carefully drawn up so as to secure uniformity on the part of the reporters, and they contain full instructions." Mr. Jonathan Hutchinson heads the committee, which contains the names of many of the best known men among the English surgeons.

A somewhat similar proposition comes from Braatz, one of the assistants at the Heidelberg Clinic, who, while reviewing a paper by Djaknow, on the "Explanation of the Clinical Evidences Accompanying Death from Chloroform,"[1] calls attention to the fact that, no less than seven years ago,[2] he proposed that permanent Chloroform Committees be instituted, whose duty it should be to carefully examine into and report upon all deaths attributable to an anæsthetic. It goes without saying, that these committees should be made up of men prominent in their own communities. They would report at stated intervals, and their proceedings could find publication in a designated periodical.

Such a work of investigation could, in this country, be very well undertaken by committees appointed by such a representative body as the American Surgical Association.

There could be a sub-committee composed of, let us say, three men in each centre of considerable size, whose duty it should be to make careful scientific investigation of each death attributed to an anæsthetic, occurring in its territory.

These sub-committees could in turn report to the central committee, which latter body should, as said, publish its conclusions at stated intervals.

TO PREVENT ALIEN PHYSICIANS PRACTISING IN NEW YORK.

SENATOR MCCARREN, of Brooklyn, has introduced into the Legislature of this State a bill to regulate the employment of physicians by corporations having the care, maintenance, and custody of children or invalids. The bill is as follows:

"SECTION 1. It shall not be lawful for any corporation organized under the laws of this State, and having the care, maintenance, or custody of children or invalids, to make use of the services of any physician who is not a citizen of the United States.

"SECTION 2. This act shall take effect immediately."

The bill is possibly aimed at a practice said to prevail in some foreign hospitals in this city of advertising for and importing house-physicians from foreign countries.

The evil or injustice of this practice, if it is such, is not of sufficient magnitude to justify such legislation as is proposed. We understand, however, that in a short time the laws of France will make it practically impossible for American physicians to practise in that country. It is already a difficult thing to do.

We believe that if France takes such an attitude toward us we should in justice make it equally difficult for French physicians to come over here and put up their signs. Reciprocity is just.

THE METHODS OF CATARACT EXTRACTION.

AN interesting account of the methods and results of the different operations for extraction of cataract is given by Dr. D. B. St. J. Roosa in the *Archives of Ophthalmology*. The account covers the history of two hundred and six operations extending over a period of twenty years. It shows the varying changes and fashions in cataract operation. A statistical table is given, in which we find that eleven kinds of operation were used, although the great majority were done after the method of Graefe with slight modifications. After carefully trying other methods the writer adopts finally the single flap operation of Graefe without iridectomy. He very candidly confesses that an ingenious operation of extracting the lens in its capsule devised by himself had not the advantages at first supposed, and is unnecessarily difficult.

Of the cases operated upon eighty-two per cent. were successful.

In thirty-two cases the vision was restored to from $\frac{20}{50}$ to $\frac{20}{40}$. In a larger number the results range from $\frac{20}{20}$ to $\frac{20}{200}$.

The most important advance in the technique of cataract operations is the use of cocaine. Dr. Roosa does not

believe very much in antiseptics, but advocates cleanliness, boracic acid, and hot water and soap. As boracic acid is very little antiseptic, hot water and soap hardly at all, it would appear as if not much effort is used to secure asepsis.

Dr. Roosa finds that in some cases senile delirium, in others malaria may develop as the result of the operation.

The statistics given in his article are particularly valuable as showing the results of a candid study of cases continued over many years, and as giving the opinions of a conscientious and skilful operator.

CHEMOTAXIS.

The study of bacteria and their products, with reference to disease and immunity, has brought into use a new word, and there seems to be some discrepancy as to the meaning and spelling of it. The word is so new that it does not appear in Foster's Encyclopædia Dictionary nor in the Century Dictionary; yet current medical journals have to print it very frequently. If we understand it correctly, chemotaxis is the influence which certain chemical substances possess of attracting or repelling living cells. Thus the bacteria of inflammation produce a substance which attracts the leucocytes, causing purulent foci and inflammation. The term "chemotropism" is used by some; and the word chemotaxis is spelled chemiotaxis by others. "Chemotropism" is also spelled sometimes "chematropism." It would be well if the bacteriologists would get together and agree a little better upon definitions and orthoepy.

THE CARE OF THE INSANE OF NEW YORK CITY.

The committee appointed by the Mayor to investigate this subject has made its report. In brief it recommends that the city's insane be not transferred to the care of the State, that the allowance for maintenance be increased to fifty cents per week, that the Blackwell's Island Asylum be given up, and its inmates be all transferred to Ward's Island, that the city be exempted from its tax for the support of the State insane, and that the Medical Superintendent receive a larger salary with full power to appoint and discharge his assistants.

With regard to the present condition of the insane poor, the report says: "Their accommodations are a reproach to humanity. Overcrowding exists in every building of every department, and their wretched existence is rendered still more intolerable by the absence of comfortable surroundings, of proper accommodations of every kind, and by insufficient protection, in the case of many of the smaller buildings, from the inclemency of the weather. There is also the danger of fire, which in the inflammable wooden buildings would be certain to result in large loss of life."

The State care of the insane at Binghamton and Willard, except in the matter of buildings and the absence of overcrowding, and perhaps that a better quality of meat was supplied to the inmates, was not found better than that of the city, while the cost of maintenance was considerably greater. Hence a transference of the city insane to the State is not considered necessary.

One point which the Committee did not, we think, touch upon, deserves most careful attention. It is the care of the insane who are not paupers but cannot pay for private treatment. There is a very large and deserving class who do not want their friends in a pauper institution, and who can afford to pay the price of maintenance and a little more, say $5 or $6 per week. At present such people have no choice between private and pauper asylums, unless they go to a State institution, and this will not be possible probably after the city is exempted from its State tax.

A STUDY OF MORALITY.

Dr. Albert Leffingwell has published a little work on the subject of illegitimacy which has value as a social and medical study. He has investigated chiefly the statistics of Great Britain and Ireland, and he shows that within these islands a great diversity in sexual morality exists. Thus while in some parts of Scotland, out of 1,000 unmarried women, about 20 give birth every year to children, in Ireland the ratio is only about 5 per 1,000. Or, put in another way, the ratio of illegitimate to legitimate births ranges from 80 per 1,000 down as low as 10. The average for Great Britain is about 40 illegitimate births to 1,000 legitimate. The ratio is greater in rural than in urban populations; it is greater in certain counties than in others. The rate is a pretty constant one, year by year, though statistics show it to be gradually decreasing.

After a careful analysis of all the possible factors in increasing or decreasing immorality, Dr. Leffingwell comes to the conclusion that the essentials are these: religious teaching, the ease or difficulty in marrying, heredity, racial traits and tendencies. He dwells on the fact that immorality is a constant and fairly regular social factor; so that one can say that in New York City, for example, there will be in the present year 1,500 to 2,000 unmarried women who will give birth to children.

As immorality brings disgrace, shame, and unhappiness, to the mother, and perhaps to whole families, and as it leaves a stain upon the child, Dr. Leffingwell naturally discusses the question of remedies. In the making the marriage ceremony an easy one, the enforcement of some responsibility for paternity, and the inculcation of proper moral and religious principles in the young are the measures dwelt upon and recommended.

The Statue to Dr. J. Marion Sims, which is a full-length figure in bronze, nine feet in height, has arrived in this city and will soon be ready for the inspection and approval of the Committee on Statues of the Central Park, after which it will be duly presented to the city. The sculptor Ferdinand V. Miller, of Munich, Bavaria, has not only succeeded in making a life-like picture of the distinguished gynecologist, but has given an artistic grace to the pose which will challenge criticism. The pedestal, which will be of granite and eight feet in height, has been especially designed by the same artist, to be in harmony with the lines and purposes of the figure. It is expected that the monument as a whole will be completed and placed in its position within the present year, as a lasting tribute to the subject by the members of the profession in this country and other patrons of the civilized world.

News of the Week.

The Cost of a Name.—There is a good deal in a name, according to Dr. H. A. Hare, who says in the *Therapeutic Gazette:* "Perhaps no better example of the price which can be put upon a name can be found than in the example before us. Diuretin (Knoll) costs $2.50 an ounce, but sodio salicylate of theobromine (Merck) costs fifty cents an ounce, or one-fifth as much. At the dose of two drachms a day the drug at the first price becomes an impossibility to many persons—an advantage in a name to a patentee and a disadvantage to the long-suffering public—while at the latter it is purchasable by a large number. These notes are not made as a final report, but only to point out the fact that the drug sometimes fails to do all that has been claimed for it."

The Best Way to Give Cod-liver Oil in tuberculosis, according to Professor Charteris, is this (*Lancet*): It should be prescribed in a teaspoonful dose at bedtime for three successive nights, then a dessertspoonful at the same time. On the sixth and seventh days it should be taken in a dessertspoonful dose after dinner and at bedtime, and afterward in a tablespoonful dose after each meal. If so prescribed it does not cause eructation or nausea, and the doses may be increased in accordance with the wishes of the patient until the end of the fifth week, when it should be stopped for a week, and resumed. With each dose of the oil five grains of hypophosphite of lime dissolved in a little hot water should be taken. Thus administered, these medicines notably increase the strength of the patient, and returning health is evidenced by increased weight. If circumstances permit, and if the patient be young, a sea voyage is of inestimable advantage in maintaining the progress made to recovery, and if the voyage be to New Zealand and back in many cases the patient's health is established. I firmly believe that the hypophosphite of lime is the only form of hypophosphite of any value in tubercular disease.

Parisian Methods of Treating Pneumonia.—Dr. Dujardin-Beaumetz, in a great many cases of pneumonia uses no remedy whatever, interfering only when complications occur, such as weakness of the cardiac apparatus as the result of a previous infective disease or of alcoholism. In such instances he employs caffeine hypodermically, not approving of the alcoholic preparations, but regarding coffee, tea, and kola as useful. Against nervous symptoms and delirium he employs chloral, and in alcoholic patients paraldehyde in the dose of forty-five grains, but he never uses opium under any circumstances. Blisters are never used by him in the acute stage of the disease. Professor Cornil recommends the use of an antiseptic mouth-wash, and when the local signs of pneumonia are great at the beginning of the disease, orders several wet cups, or resorts to venesection if the pulmonary congestion is severe. He then applies a large blister and gives a mixture as follows:

℞. Brandy or rum	℥ iss.
Simple syrup	℥ j.
Tincture of cinnamon	℥ j.
Distilled water	℥ iij.

A tablespoonful of this mixture should be taken as often as is necessary to strengthen the pulse. He also orders a little Dover's powder to increase perspiration. Professor Peter thinks that robust and plethoric patients demand the use of venesection and scarifying cups, while the weak and senile must receive cordials, such as the prescription just given, and the bilious must be treated by emetics, such as tartar emetic or antimonium sulphuret, in the dose of from four to five grains. Most other physicians agree in using as stimulants caffeine, ether, alcohol, and camphor. Digitalis is not much used, nor is hydrotherapy at all popular.—*Therapeutic Gazette.*

A Medical Treatment for Appendicitis.—Professor Peter's early treatment of typhlitis and perityphlitis has proved on several occasions very efficacious. As early as possible six scarified or wet cups are placed over the tumor, or, preferably, a large number of leeches are applied in the same region. On the next day after the local blood-letting, the temperature generally falls and the pulse diminishes in volume.—*Therapeutic Gazette.*

The Association of Military Surgeons of the National Guard.—The second annual meeting of this association will be held in St. Louis, Mo., April 19, 20, and 21, 1892. Papers will be read and discussed by regular Army and Navy and National Guard medical officers.

The University Medical College of this city graduated a class of one hundred and sixty-two at its annual commencement last week.

Reviews and Notices of Books.

A Treatise on Diseases of the Lungs and Pleura. By the late Wilson Fox, M.D., F.R.S. Edited by Sidney Coupland, M.D., F.R.C.P. Philadelphia: P. Blakiston, Son & Co. 1892.

This book embodies, we may say, the combined thoughts of almost every living author to date, and goes into especial detail upon the most obscure points which a careful student seeks.

Here we find the pathology and bacteriology especially dwelt upon. The article on Pulmonary Tuberculosis is so carefully written that the etiological relationship between it and bacillus tuberculosis is clearly established. What has been said of Pulmonary Tuberculosis may be said of all other chapters, which are treated in an exhaustive manner. It is of especial mention, and for this reason the book will be highly welcomed by the general practitioner, for the treatment of pulmonary diseases is one about which too much cannot be written, considering the enormous mortality caused by the same.

To the specialist, the article on the Climatic Treatment of Tuberculosis is highly instructive reading. The illustrations deserve special mention, for they are very finely executed, and especially in the article on Plastic Bronchitis, the casts shown are neatly executed. In the article on Asthma we find a neat illustration of the octahedral crystals from the sputum, and also some cells, presumably the eosinophile cells recently described by Professor Leyden, of Berlin.

In the chapter on Pneumonia, which is also replete with illustrations and charts and tables, a great deal can be learned. The articles on Influenza and Whooping-cough are very interesting—the latter a masterly article, although no notice of bromoform, which has been extolled in this country and abroad as almost a specific in pertussis, is made.

On page 103 we find, in the article on Influenza, "the theory that it is due to germs or fungi still requires facts for proof." This is written in 1891. How science advances is shown by the conclusions of Pfeiffer and Covon, who but two months ago discovered almost simultaneously

been thoroughly revised and brought up to date in most respects, but it is rather singular that the author has devoted so little space to the consideration of the mode of producing local anæsthesia of the skin and tissues other than the mucous membranes.

Botany: A Concise Manual for Students of Medicine and Science. By Alexander Johnstone, F.G.S., Lecturer on Botany, School of Medicine, Edinburgh. With One Hundred and Sixty-four Illustrations and a Series of Floral Diagrams. New York: D. Appleton & Co. 1891.

We cannot agree with the author of this book when he asserts in his preface, that "no one attempts to teach himself science nowadays," and that, therefore, what is wanted by the modern student (in this specific case of Botany) is not "a manual with diffuse explanations, but rather a kind of illustrated digest and general note-book, which will enable him to quickly arrange and make the most effective use of the various facts and theories treated of by his teacher." No one would by preference teach himself science if he were able to avail himself of the guidance of a teacher, at least when taking his first steps; but everyone is not so fortunately placed, and many men, if they would learn at all, must teach themselves from books and observation in the absence of a living instructor. Mr. Johnstone has aimed, he says, to construct such a text-book as may be useful to learners who have been, or are, members of a class in botany. In this he has succeeded admirably, and we can readily believe that anyone attending a systematic course of lectures on Botany will find this work most useful, in enabling him to recall and stamp firmly in his memory the points brought out by the lecturer. But the author is too modest in restricting the field of usefulness of his book, for the text, though concise and reduced to almost the last equation of brevity, is nevertheless so clear and clean-cut, and so happily supplemented by the illustrations, that anybody, whether he has previously studied Botany or not, cannot fail to derive instruction from its pages. For one ignorant of the science it will serve as a work of reference, while the former student who has become a little rusty will find his knowledge of botany brightened and made as good as new by this lucid summary of the beautiful science. A fairly complete glossary and index enhance the usefulness of the work, especially for the two classes of readers just mentioned.

The Etiology, Pathology, and Treatment of Diseases of the Hip-joint. By Robert W. Lovett, M.D., Out-patient Surgeon to the Boston City Hospital; Assistant Surgeon to Out-patients at the Children's Hospital, Boston; Member of the American Orthopedic Association. Boston: Geo. H. Ellis. 1891.

This is an essay to which was awarded the Fiske Fund Prize of the Rhode Island Medical Society in June, 1891. The author takes up the various affections of the hip-joint, including the rarer forms, such as Charcot's disease, congenital dislocation, and neuromimesis, each in its turn, and treats of them very fully and satisfactorily within the limits set by the trustees of the prize fund. For the sake of completeness, however, it is to be regretted that a consideration of the symptomatology of hip diseases should have been omitted, since upon a correct diagnosis depends the successful management of these cases. The illustrations, of which there are over fifty, are for the most part from photographs, and have been selected with nice discrimination. The addition of the omitted sections on the symptoms and diagnosis is all that is needed to make this a very valuable treatise on diseases of the hip.

The Mediterranean Shores of America. Southern California: Its Climatic, Physical, and Meteorological Conditions. By P. C. Remondino, M.D. (Jefferson), Member of the American Medical Association, of the American Public Health Association, of the San Diego County Medical Society, of the State Board of Health of California, etc. Philadelphia and London: The F. A. Davis Co. 1892.

We don't like the title of this book. It is as repellant as Charles Dudley Warner's "Our Italy." No one who has experienced the horrors of the mistral on the Riviera, or the torture of a cold day in Roman lodgings, would ever be tempted to visit Southern California if he thought such names were justly applied. Even the most luxuriously cushioned arm-chair will tempt few sitters if it is known that the upholsterer has left several bent pins concealed in the soft and springy seat; and the sensible pilgrim really in search of a mild and equable winter climate will not knowingly go to a place where he is exposed to the stings of even occasional cold days. For this reason it seems to us that the title does injustice to the subject of the work.

But now for the book itself. It is a very fair and temperate description of the climate of Southern California, well written, interesting, and reliable. While the author is evidently himself in love with the climate and believes it among the best, if not actually the best on earth, yet his book is pleasantly free from the cure-all style of the climate boomer. Dr. Remondino believes in the climate and he wants others to know and appreciate it, but he lets his subject speak for itself and does not try to bolster it up by exaggeration. The introduction contains a brief essay on medical climatology, and more especially the relation of temperature and altitude to consumption. The illustrations, of which there are many, are derived from various sources, and are of very varying degrees of excellence.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent).

THE HUNTERIAN LECTURE—DR. HUGHLINGS JACKSON ON NEUROLOGICAL FRAGMENTS—THE CEREBRAL CHANGES IN DELIRIUM AND INSANITY—LARYNGEAL CRISES—REGULATION—CEREBRAL AND CEREBELLAR INFLUXES—THE MORBID CHANGES IN CEREBRAL HÆMORRHAGE—DISCUSSION ON ENTEROSTOMY AT THE MEDICAL AND CHIRURGICAL SOCIETY.

LONDON, March 12, 1892.

In the Hunterian Lecture recently delivered before the Hunterian Society, Dr. Hughlings Jackson discussed several interesting points in neural pathology under the title of "Neurological Fragments." Teeming with facts and illustration, as is the case with all Dr. Jackson's contributions, the lecture is not one which can be summarized in a few lines, and I can only briefly refer to a few of the topics brought before the Society by Dr. Jackson in his elaborate and suggestive address. The first part of the lecture was devoted to the subjects of insanity and delirium. The lecturer said he had often thought that the scientific investigation of insanities might be best begun in general hospitals, and especially by taking for study cases of delirium in such non-nervous maladies as pneumonia and emphysema with bronchitis. These were not insanities at all in the conventional sense of the word, but in a scientific regard they were, as they were departures from normal mental states. After the late Dr. Monro, he had urged that the mental condition in all insanities short of dementia was double—one of two opposite mental elements. In cases of emphysema with bronchitis we could observe a gradual losing touch with present surroundings (negative element), and a gradually increasing quasi-relation to organized experiences of former surroundings (positive element). Using popular language, the patient gradually ceased to live in the real world and came to live more and more in a world of his own. The lecturer then adverted to the physical condition concomitant with insanities—the two abnormal cerebral states corresponding to the two abnormal mental elements. The negative mental state, he said, signified loss of function of the highest range of the highest cerebral centres. The positive element of an insane man's mental condition signified evolution going on in lower intact ranges of his highest centres. He attributed the two degrees of insanity in cases of emphysema partly to great supervenosity—to different degrees of it. It was certain that supervenous blood over-stimulated some lower (*e.g.*, medulla) centres. The obvious explanation of the delirium in cases of emphysema with bronchitis would be that it corresponded to over-stimulation of cerebral centres. Asphyxia, however, rendered the motor cortex inexcitable. It did not follow that asphyxia rendered the remainder of the cortex functionless. Dr. Jackson suggested, however, that supervenous blood, according to its degree of venosity, diminished or annulled the function of all parts of the cortex. If so, it could not be the cause of delirium, which implied function going on. He suggested that the course of events was as follows: The highest, the least organized, range of the highest centres was rendered functionless at first (by supervenous blood), while the lower and more strongly organized ranges of those centres remained functionable. The lower ranges being now uncontrolled rose in activity, and during their activity delirium occurred. When the supervenosity became very great the lower ranges of the highest centres also succumbed, and then no sort of mentation was possible—not even that disorderly mentation which we called delirium. He admitted that the condition was probably more complex than this in reality, for from highly supervenous blood there would be very great stimulation, and perhaps ultimately exhaustion of lower (medulla) centres. He had suggested elsewhere that great supervenosity might cause loss of the knee-jerks, as when there was great cyanosis in severe cases of emphysema with bronchitis, and that possibly the absence of this tendon reaction in some cases of apoplexy was thus caused.

Passing on to other subjects, Dr. Jackson remarked that he had (in a paper read before the Hunterian Society) submitted that the paroxysms in laryngismus stridulus were asphyxia fits, analogous to those producible artificially in rabbits and dogs, and were due to interference with respiration from softened (rickety) ribs causing overstimulation of the respiratory centre by supervenous blood—convulsions resulting. He now discussed this subject in greater detail, and also that of asphyxia in laryngeal crises. In these there might be loss of consciousness and some degree of convulsion, as in a patient now under his care. He suggested that if, as Semon thought, there was in these cases an "irritative" state of the (medulla) adductor centres, laryngeal crises were due to occasional overaction of these centres by which the glottis was greatly narrowed or even completely closed.

The lecturer then reviewed the subject of "Regulation" (nervous, mechanical, chemical), and referred to his theory of cerebral and cerebellar influxes. The lecture was brought to a conclusion by discussing the changes which occurred in cases of cerebral hemorrhage. Referring to "cerebral fever," Dr. Jackson said he thought it depended on secondary effects the clot produced in medulla centres; he thought that morbid changes were set up akin to those of optic neuritis. In a case of large cerebral hemorrhage it was convenient to distinguish several modes of action of the escaped blood. Thus (1) it destroyed tissue, and thus produced such symptoms as hemiplegia; (2) it caused shock—varying with the rate of its escape; (3) according to its bulk it squeezed and thus produced loss of consciousness; (4) in its character as a "foreign body" it might produce encephalitis, and thereby, hypothetically, "cerebral fever," by changes induced in medulla (regulating) centres; finally, (5) in some cases of cerebral hemorrhage in which consciousness, if defective, had not been lost at the outset, delirium might occur, and he submitted that this was mainly a "return effect" on the brain, a consequence of imperfect working of the respiratory and other organic systems, a state of things analogous to that in the delirium of some cases of emphysema with bronchitis, and in some cases of cervical fracture-dislocation of the spine.

The last meeting of the Medical and Chirurgical Society was occupied with a discussion on "Enterostomy in Intestinal Obstruction," on which subject Mr. James Greig Smith, of Bristol, read a paper. He advocated operative evacuation and drainage of intestinal contents in cases of obstruction of the bowels where distention was a marked feature. Mere over-distention was a potent factor in the production of obstruction, and the operative treatment of intestinal obstruction was not complete till this continuing cause was removed. According to the nature of the case the measures adopted should be: (1) Simple evacuation of contents with immediate return of the gut; or (2) evacuation with drainage for several hours or days, and subsequent closure and return of the gut; or (3) evacuation with drainage that might be permanent. These procedures were discussed in detail. Mr. Smith thought that anæsthesia should never be carried out while the stomach was distended with fluid; the stomach should be artificially emptied, or the operation should be performed by the aid of local anæsthesia only. The measures advocated were intended to supplement and complete the ordinary surgical methods for relief of the strangulation, and in no sense to replace them.

Mr. Bryant said he fully agreed with the author as to the evil effects of over-distention of the bowel. After relieving a strangulated hernia the symptoms sometimes persisted and death followed; this was due probably to the paralysis of the strangulated knuckle of gut being unable to allow the over-distended gut above to empty itself.

Relief in such cases would probably be procured by a small enterostomy if only a diagnosis could be made. He had in three cases obtained satisfactory results by tapping the over-distended bowel when it had been impossible to return it within the abdomen.

Mr. Knowsley Thornton drew attention to the importance of applying firm pressure to the abdominal walls after operation in these cases, owing to the abdominal muscles having lost their tone.

Mr. Pearce Gould suggested that some poison was probably absorbed in these cases which was particularly dangerous to the patients during the administration of chloroform, and he pointed out the good effects of washing out the stomach in cases of fecal vomiting. In some cases of acute intestinal obstruction, although the operation might remove the cause of the obstruction, the patient might never recover from the effects of the anæsthesia but die soon after.

Mr. Thomas Smith said he was glad to find that the author laid such stress on the importance of reducing the length of time of administration of the anæsthetic to the shortest possible. He had long realized that manipulations of the stomach and intestines produced little or no discomfort, even when no anæsthetic had been given, and mentioned examples. It was a decided advance to be able to divide an operation of this kind into two stages—the first to afford immediate relief; the second to remove the cause of the obstruction. "Paul's tubes" were of value.

Mr. Howard Marsh observed that in some cases of strangulated hernia, though the bowel was released by operation, yet life was not saved owing to the paralysis of the part of the intestine implicated. Some surgeons had advocated resection of this part in these cases. He asked the author if he did not think the difficulty could be overcome by tapping the over-distended gut some way above the point of strangulation.

Mr. Rickman Godlee mentioned a case in which he had operated for umbilical hernia without an anæsthetic and the patient did not pay much attention while the intestines were being handled but only while traction was being made on the neck of the sac.

Mr. Greig Smith then replied. He said the necessary steps in an operation for intestinal obstruction were: 1, The stomach to be completely emptied; 2, the patient to be anæsthetised as lightly as possible; 3, an incision not exceeding three fingers' breadth in length to be made where required; 4, the sutures to be inserted, their ends collected in two clips and held aside; 5, the anæsthetic to be discontinued; 6, the cause of the obstruction to be quickly sought for and removed; 7, the over-distended gut higher up to be relieved, for which purpose he used a Spencer Wells ascites needle, attached to an aspirator bottle in which the pressure was only moderate (the contents of the intestine might come away directly or it might be necessary to wait half an hour or longer); 8, after withdrawing the needle, to close the puncture wound with a Dupuytren's suture and allow the bowel to drop back into the abdomen if sufficient relief had been obtained; or 9, if not, to keep the coil of intestine that had been punctured in contact with the opening in the abdominal wall by means of a stiff skewer passed under it or through the mesentery (stitches were unnecessary); 10, to dress the wound with boric acid and boric acid lint; 11, to firmly bind the abdominal wound with strapping so as to avoid what was perhaps the most serious risk, viz., prolapse of coils of intestine. He did not approve of leaving a tube in the intestine for drainage purposes as it was liable to cause a secretion of mucus which was injurious, but preferred to tap as many times as might be necessary to relieve the distention.

German Otological Society.—It is proposed to establish a German Otological Society, and a meeting for the purpose will be held at Frankfort-on-Main in Easter week.

THE HEALTH RESORTS ON THE RIVIERA.

(Continued from p. 389.)

IV.—General Observations on the Riviera Climate.

(From our Special Commissioner.)

THE TWO RIVIERAS—WHY THE RIVIERA ENJOYS AN EXCEPTIONAL CLIMATE—NOT AN IDEALLY PERFECT WINTER—GENERAL CHARACTER OF THE RIVIERA WINTER—PHYSICAL GEOGRAPHY—THE TEMPERATURE—SUDDEN CHILLS—ABSENCE OF FOG—THE JOURNÉE MÉDICALE—THE WARMTH OF THE MEDITERRANEAN SEA—SUNSHINE AND CLOUD—RAINFALL—HUMIDITY.

Mentone, March, 1892.

Before continuing with the detailed account of the principal health resorts scattered along the seaboard of the Maritime Alps, it may be well to make some general remarks applicable to the whole region.

The term Riviera, derived from the Italian for coast, really belongs to the entire north shore of the Mediterranean, from Marseilles, in France, to Leghorn, in Italy. Common usage, however, has given it a more restricted meaning. By this lesser Riviera, then, we designate only a narrow strip of land containing the most famous winter stations, and extending from Hyères on the west to Genoa on the east. This is a distance of about two hundred miles only. A further subdivision is made by differentiating between the Western or French Riviera (*Riviera di Ponente*) and the Eastern or Italian Riviera (*Riviera di Levante*). This whole district is situated between 43° and 45° north latitude, and it is, therefore, at once apparent that the warmth and mildness of its climate are not the result of southern latitude merely.

The altogether exceptional climate of the Riviera is due in great measure to the protection afforded by a series of mountain ranges, that in some places run down to the very border of the sea. At some of the most favored winter stations there is an almost complete immunity from those icy winds prevailing farther northward. Again, the immediate proximity to the Mediterranean Sea, whose restless waters are unusually warm and salty, is a contributing factor of no mean importance. And, finally, the great frequency of clear skies and brilliant sunshine, coupled with a dry atmosphere, result in a generally warmer and more equable temperature than is found in much more southern latitudes.

But there is a reverse side to every shield. The very factors which conduce to great warmth also account for the sudden chills that are constantly experienced the moment shade succeeds to sunshine. And the decidedly annoying and, at times, positively dangerous winds are likewise caused by the rush of cold air to the overheated shorelands, wherever a break in the mountain barriers permits such access.

In the words of Dr. Bennet it is well to remember that winter is by no means avoided. The descriptions of the winter climate of Nice, Cannes, Hyères, and of Italy in general, contained in most books of travel, works on climate and guide-books are mere poetical delusions. The perpetual spring, the eternal summer, the warm southern balmy atmosphere, described to the reader in such glowing terms, only exist in the imagination of the writers. These stupidly exaggerated accounts are to blame for the invariable disappointment that foreigners experience on becoming personally familiar with the actual condition of the Riviera climate.

Of course the general features of this climate have been thoroughly studied and are now quite well known. And, as just intimated, it is neither an ideally perfect one, nor yet, as many believe, a particularly hot climate. Nevertheless, those who have apparently found such sweet solace in utterly condemning the Riviera have signally failed to point out where a more accessible or far superior winter climate is to be found.

It should also never be forgotten that, however familiar we may be with the general character of a particular

climate, exceptional seasons must be encountered which will rudely upset all prognostications based on previous ones. For weather is not climate, as New Yorkers have reason to know.

In order to obtain an adequate idea of the climatic peculiarities of a given district, we ought to consider the following points:[1] 1, Temperature and the character of its variations; 2, the proportion of sunny days to rainy ones, of clear skies to skies that are overcast; 3, the number of rainy days, and (what is of less importance though usually much insisted upon) the amount of rainfall; 4, the humidity of the atmosphere; 5, the prevailing winds, their character, and the amount of protection from them.

To these points, which are those given by Dr. Yeo, it is proper to add some consideration of the local flora, since that is bound to furnish most important clues. Indeed, no better general idea of the amount of winter warmth and permanent shelter enjoyed at a given spot could be obtained than by a study of its vegetation. Humboldt was probably the first to insist on this cardinal point, and as de Candolle puts it, "*les plantes ne choississent pas leurs conditions; elles les subissent ou elles meurent.*"

Fonssagrives has also very aptly said that plants are not alone living thermometers, but that they are reliable vitalized climatometers.

It is necessary to consult one's geography, before the general features as well as the numerous local peculiarities of the Riviera climate can be properly understood. A map in the hand is worth ten Riviera letters, even in the RECORD. In fact, I think a map ought to go with every letter. The trouble is, the editor will probably say "think again" to my brilliant proposition. So that, since he is cock of the health-walk, it will have to be my ambition to "make the letters go" without the maps.

The Apennines and the Maritime Alps constitute the chief protecting barriers of the Riviera against northern cold. But many winter stations are still further sheltered by additional mountain ranges, and by lower hills that often run down to meet the very bays on which the towns and villages are built. The Western Riviera is much more favored in this respect than the Italian Riviera, and once beyond Genoa, the distant Alpine barrier becomes a mere fiction, so far as real protection from cold northerly winds is concerned.

Dr. Bennet, for many years a resident of Mentone, has clearly set forth the degree of protection given by the various mountain ridges:[2] "The Alps and Apennines form an immense screen to the northeast. The Swiss Alps, which terminate rather abruptly in the plains of Piedmont by the grand Alpine heights of Mont Cenis, Mont St. Bernard, and Mont Simplon, are continued in Savoy and Dauphiny down to the Mediterranean at Toulon, Hyères, Cannes, and Nice. From Nice the mountain range, which then takes the name of Maritime Alps, skirts the shore of the Gulf of Genoa in a northeasterly direction as far as that city, and in a southeasterly direction as far as Lucca. At Genoa it unites with the Apennines, or rather becomes the Apennines."

Italy is, therefore, less sheltered than the Rivierian littoral, and its climatic health-resorts are only found on the western sea-coast, and certainly not beyond Pisa.

From the above it appears that, what is technically known in the art of gardening as an "espalier," nature has accomplished on a grand scale on the Riviera. More than this brief excursion into the tiresome domain of physical geography is unnecessary. But that much, and a great deal more is the inevitable penance which the nouveau Riviera climatologist is doomed to undergo. And, as I hope to show later on, there is plenty of other torture in store for the conscientious student of health matters in this part of the world.

[1] See J. Burney Yeo: Climate and Health Resorts, p. 378. 1890.
[2] Winter and Spring on the Shores of the Mediterranean, p. 5. London, 1875.

The thermometer has been much sinned against along the Riviera. It has been made to proclaim every place better than all neighboring ones by its enforced subserviency to the dictates of tyrannical local registers. Anything more futile than the attempt to get at the truth from the numerous contradictory records that confront you I have not yet come across. Most Riviera books are over burdened with dreary tables of means and extremes, of averages and maximums, of minimums and other variations, that only bemuddle when elucidation is needed. Most of these tables have a knack of shedding deep darkness precisely in those places where light is most wanted. To take, as has been generally done, thermometrical readings at stated intervals, say of about four hours, and then work out an elaborate system of averages is so puerile a performance that it seems strange how one medical authority after another could have fallen into this faulty method. Yet such is the case, with (so far as I am aware of) very few exceptions. Dr. Onimus has boldly stated,[1] and I am fully prepared to agree with him, that it might be an advantage to pass a sponge over all the thermometrical records usually published in works of reference on the Riviera.

Patients are sent to the sunny South to be as much as possible exposed to direct solar rays. Yet most thermometrical records subserving meteorological purposes are taken in the shade, and generally facing northward. Teysseire has, however, furnished figures which compare the temperature of spots fully exposed to sunshine with those remaining in the shade, and I will presently give some of his observations. But before doing so the method employed by Dr. Onimus should be mentioned. This observer uses an apparatus with which the variations of temperature are graphically traced by a simple self-registering device. The traces thus obtained show the hourly or half-hourly variations for the entire period of twenty-four hours. Of course, every physician will be able to judge from the steep or gradual ascent of the traces how rapidly the thermometer has risen, how long the maximum temperature has lasted, when the minimum occurred, and all other important details. By carefully comparing such graphic records, temperature curves of real value can be constructed.[2]

Doubtless it is well to know that the Riviera enjoys a mean winter temperature some eight to ten degrees Fahrenheit higher than England. But it is scarcely necessary to know any other average record.

The difference between sun and shade temperature is more important however, and here are some of Teysseire's figures.

Mean temperature.	Sun.	Shade.	Difference.
In spring	146.1° F.	67.6° F.	78.5° F.
In summer	155.1° F.	82.9° F.	72.2° F.
In autumn	139.8° F.	64.6° F.	75.2° F.
In winter	128.9° F.	55.9° E.	73.0° F.

These figures are transcribed from Sparks.[3] According to them there is the considerable average difference between sun and shade temperatures of about 75° F. all the year round. This is one reason why the Riviera climate has often been found so treacherous by the uninformed and unprepared newcomers, who are apt to neglect obvious precautions.

So, too, physicians sending patients to the Riviera should surely know something of this unfortunate peculiarity.

There are always days when winter makes itself unmistakably felt, and there are hours in almost every day when a very decided sensation of cold is experienced out

[1] L'Hiver dans les Alpes Maritimes, p. 218. Paris, 1891.
[2] Good reproductions of illustrative curves are found in the work of Onimus, but unfortunately they only apply to Paris and Monaco.
[3] The Riviera. London, 1879.

of doors. Yet a glance at ordinary average temperature charts would engender the utterly mistaken notion that it is always warm in these regions. But I believe it to be very near the truth when I state that the actual sensation of cold is more keenly and disagreeably perceived here than in much colder zones. It was a Russian emperor who said that "he preferred Russian to Italian winters, because you could see the former without feeling them, whereas you felt the latter without seeing them." For a mere emperor that is not a bad observation.

The mean winter temperature of the Riviera, speaking quite broadly, is about on a level with the annual mean of New York. But the figures for New York are apparently rising, as a glance at the table of the Weather Bureau shows:

Annual Mean Temperature at New York.

1885	49.8
1886	51.0
1887	51.9
1888	50.0
1889	53.5
1890	53.6
1891	53.8

In any event, the comparison shows how absurd it is to draw conclusions from such tables. For the winter climate of the Riviera does not bear the slightest resemblance to average New York weather. In fact it would be a blessing if these misleading averages could be entirely eliminated from climatological discussions. But such is the force of bad habit that they crop up constantly, much after the fashion of other useless weeds.

The sudden sensation of chilliness experienced at sunset has been already alluded to. It has been generally attributed to an equally sudden fall in temperature. It is not a peculiarly Rivierian phenomenon, however, being met with wherever solar radiation is powerful, owing to clear skies on a scant atmospheric humidity. Dr. Onimus has conclusively shown that there is no such rapid fall of the thermometer as has been uniformly insisted upon. Indeed he finds that, thermometrically speaking, it is just about as warm at sunset as in the forenoon. Yet everybody feels warm in the morning and cold at sunset, which once more shows that the alleged teachings of the thermometer are to be taken *cum grano salis*.

Again, it is not only at sunset, but in going out of the sunshine into the shade, that these Riviera chills always creep over you.

A few words will suffice in explanation of the way the human body is affected by radiation, and how this physical law accounts for the disagreeable sensation alluded to. In the absence of aqueous vapor in the air solar radiation becomes powerful, because dry air is a good conductor of heat. All bodies, even animated ones, tend to give up part of their store of accumulated heat the moment they are plunged into shade. Of course the automatic heat regulation of the body prevents any material fall of interior temperature. But the surface is actually cool, and feels subjectively even cooler, the moment it has ceased to be exposed to the sun. If you were to leave the hot-room of a Turkish bath and take the cold plunge at once, you would experience just about the same thing that almost unavoidably happens to you several times a day on the Riviera. There occurs on every such occasion a rapid abstraction of caloric, which is responsible for a profound and sudden sensation of cold.

A heavy precipitation of dew (a very necessary boon to vegetation, that without it would soon be parched to death) is one of the results of what has just been briefly explained. And for the same reason the atmosphere, especially near the earth's surface, may grow so hazy that it seems to hold a fog. Yet this is not the case, for true fogs, such as occur in moist marine climates, are practically unknown on the Riviera.

On the other hand, when cloudy skies obtain solar radiation does not take place, and this explains why on such days the evening chill is not felt.

The invalid's day, or, in other words, the hours during which he is advised to be out of doors, have been generally set down to begin at ten or eleven o'clock in the morning and to end at from two to three o'clock in the afternoon. But Dr. Onimus has found that the temperature is lowest immediately before sunrise, and that so soon as the sun appears it gets warm with such rapidity that an almost perpendicular line is traced on the register. In different months and at different places there are variations in this respect, but in any event the best time for going out can be safely put down as at least one hour earlier than has been generally done. A contributing factor to the winter warmth of the littoral is found in the temperature of the Mediterranean Sea. This is stated by Dr. Marcet to be 12° F. higher than the mean minimum of the air. He says: "The temperature of the air near the Mediterranean must derive a considerable accession of heat throughout the winter from that which is stored up by the water during the summer; and this may be considered one of the most powerful agents to which we are indebted for the comparatively mild winter temperature of the South of France."

All observers agree in saying that the Riviera merits its long-established reputation as a land of brilliant sunshine and clear skies.

Sparks gives the following averages, based on different observations extending over a period of something like forty years:

Number of Rainy Days.

	Hyères.	Cannes.	Nice.	Mentone.	Genoa.
November to April (both inclusive).	37.5	45.8	36.2	43.5	67.0

From Teysseire the following figures are borrowed: 64.7 days of rain per year; 86.5 cloudy; 208.5 clear.

For a region bordering on the sea the Riviera is certainly very dry. The number of rainy days is decidedly less than in many other coast lands. Merely overcast days are likewise comparatively few. When rain finally falls, however, it generally does so in a pour rather than a mere sprinkle. But even after a thorough drenching the sun's heat rapidly restores the *status quo ante* in regard to dryness.

Concerning the distribution of rainy days, it is of course impossible to speak in any other than a very broad manner, which will have to cover numerous seasonal departures. Still one must expect rain in October and November, less in December, and least of all in January and February. March is very uncertain, and in April there is usually again a decided increase in the number of wet days, as well as in the actual amount of rainfall.

Thoroughly cloudy days and days of incessant rain are said to be rare on the Riviera. But this winter's experience has shown me that the sky may remain completely obscured for six successive days, and that a steady drizzle may take place that no New Yorker will fail to spot as a reminder of home. Naturally, local authorities all inform you that this has been an exceptional season. They always tell you that in Europe, when anything happens to the fair weather that they put in all their books. I don't believe an author could find a publisher here for his observations if they happened to include any really disagreeable weather. There is something quite touching about all this everlasting sunshine one reads about, especially when one has not had an opportunity of seeing his solar majesty for something like two weeks in succession.

The actual amount of winter rainfall on the Riviera is almost double that of London, and considerably in excess of that of Paris or New York. But, as already stated, the number of rainy days is very much smaller. Especially with southwesterly and southeasterly winds

the rainfall may be almost tropical in character. Some five or six, or even more, inches may then be poured down in the twenty-four hours. "Whenever this occurs, the watercourses are filled from bank to bank, with enormous volumes of water, which carry down great masses of stone, like straws, from the mountains, and excavate wide beds as they approach the shore-line. When the rain falls with this tropical violence the smallest rills become impetuous torrents."

It is stated on good authority that the average annual rainfall at Nice, representing the Western Riviera, is 811 millimetres; at Genoa, representing the Eastern Riviera, 1,317 millimetres; at Hyères it is only 746.

That the Mediterranean seaboard enjoys an exceptionally dry climate has been already stated. Dr. Bennet has briefly enumerated the causes leading to this condition, viz.: prevalence of northerly winds, the great power of the sun, the freedom from fog, the small number of rainy days, and the dry, rocky character of the soil.

The dryness of the whole region may also be ascribed to the circumstance that the littoral represents the northern boundary of the "rainless tract."

As regards moisture in the air, saturation should not be confounded with humidity. The latter represents the amount of aqueous vapors contained in the atmosphere as compared with what it might hold if it were fully saturated at the same temperature. Humidity denotes rather the tendency of the vapor to precipitation. Now, the air along the Mediterranean is never saturated. This is accounted for on the ground of the large proportion of salt contained in the sea-water (Onimus).

There is certainly, as everyone knows, a decided difference between the clammy penetrating sensation of humidity experienced on the shores of sweet-water lakes and the corresponding sensation felt along the beach of salt-water oceans.

If we take one hundred to represent saturation, then the Riviera humidity might be placed at about seventy for the winter months. The figures in New York often get up into the nineties, and the ordinary London average is very nearly ninety.

That the skin and even the lungs will give off a relatively large proportion of aqueous vapor is thus easily understood. And I believe that certain renal affections may be much benefited by the judicious use of a climate promoting the compensatory activity of the cutaneous surface.

This letter has now reached such length that the Riviera winds and vegetation will have to be considered in my next.

WHAT CONSTITUTES INEBRIETY.

To the Editor of the Medical Record.

Sir: In the Medical Record for March 19, 1892, Dr. C. L. Dana is not accurate when he writes, referring to Dr. Norman Kerr on "Inebriety," "He seems to include nearly every person who drinks, and at times gets drunk, in this class." I would call attention to Kerr on "Inebriety," second London edition, page 16, where these words will be found: "The majority of those who drink are happily not susceptible to its anæsthetic action; but in virtue of an unalterable law of nature there are large numbers whose susceptibility to the narcotic properties of this poison is so delicate that, though they are fully conscious of their weakness, and sick unto death of their slavery, once dally with an intoxicant they fall prostrate before its might." Also on page 16: "Therefore I freely concede that if there is inebriety the disease, there is drunkenness the vice and the sin." In common with others who have long observed people and their families, and have studied individual cases and their family histories as general practitioner, I have, after twenty-five years' general practice where I was born, and where my father was born in 1797, and where he lived ninety years, arrived at certain conclusions regarding inebriety as distinguished from ordinary drunkenness. I have also had special opportunities to study inebriety, and to compare it with some forms of insanity. Without wishing to be tedious I can hardly help referring to two cases of recurrent mania, in which the drama of intoxication in three acts was watched with interest. It made me think of Dr. Clouston's idea of inebriety, "Unstable condition of the brain-cells, with paralysis of control."

C. P——, aged fifty-five; chronic monthly recurrent mania. Attack always began with great excitement, acting like alcoholic in first stage; face flushed, quick and loud talking, gait somewhat unsteady, and anyone without knowing would simply think him drunk. He would be noisy for days and nights, requiring extraordinary doses, which would hardly quiet him; but after some days he would become quieter, then stupid, and sleep as one in last stages of a drunken debauch.

A. B——, aged fifty-two, temperate, religious, and, when himself, a fine man, had recurrent mania of most intractable character. If kept quiet would go a year without attack, but overdoing would precipitate one, which would last nearly a year. Face flushed, loud talking, swearing, and whole character changed. He said to me: "Doctor, I am just like a man on a spree, I must have it out. I knew it had got to come, it don't hurt me to talk, and I am going to talk."

Inebriety is a complex disease and needs to be watched over a long period of time to form conclusions regarding it. Its accidents, and those of ordinary drunkenness, as delirium tremens, etc., few differ about, and we all know that pathological results do not cause the disease, for some who have died by accident have been found as organically sound by appearances as many of the insane have appeared. Because there are such an immense number of cases of plain drunkenness, we should not shut our eyes to true inebriety, and overlook it, when it exists, as has often been done. Some day it will be better understood by sheer force of circumstances, by its increase and effects, and already the tide is coming in. Before 1816 little was known of diseases of women, and when I began the study of medicine, in 1861, comparatively little was known here about diseases of the rectum, and we had to go to St. Mark's Hospital, London, to study and see the best operations. Bushe, in this country, had written the best book on the subject, but there are always pioneers. I served in Bellevue and on Blackwell's Island in 1864 and 1865, and I cannot think the cells the best place to study inebriety. Long, close, and broad observation is required. How many who see the insane come nearly to feel that many are simply vicious, and it is not so very surprising sometimes. I was much

struck by Dr. Hammond's article in the *North American Review*, more than a year ago, where he dilates on this very point. I am not running a retreat, and only write with conviction from a full head and heart.

W. A. Lockwood, M.D.

426 Vanderbilt Avenue, Brooklyn, April 4, 1892.

THE STATE MANAGEMENT OF THE INSANE.

To the Editor of the Medical Record.

Sir: While the State regulation for the management of the insane is conceded by everyone to be a necessary measure, the abuse of power by its officers can very easily work an inconceivable amount of injustice and persecution. Until the year 1889 there was but one officer whose duties were fixed by statute; and two or three medical men, who were incumbents, as a rule, sagaciously and intelligently inspected the asylums and regulated the commitment of patients. Within the last three years, however, a three-headed commission was appointed, but one member of which was a medical man, and its existence was the result of a most persecutory act of the Legislature, which practically enables this board to enact it own laws and do what it chooses, it being even beyond the mandamus of a Judge of the Supreme Court of the State. As one greatly interested in the commitment and treatment of the insane, my experience has been sufficient to enable me to watch the workings and witness the intolerance of this board that would be almost out of place in Russia.

Numerous well-informed lawyers have frequently attested to the unconstitutionality of the autocratic laws of this body, which strike directly at the root of professional confidences, the well-being of patients, and the right to practise medicine which is conferred by the laws of this State. Even the form of commitment which is issued by the State Commission of Lunacy is not only stupid and impractical, but far inferior to that framed by Dr. Ordronaux, and obliges the physician committing to betray—if he knows them—professional confidences made by members of the patient's family. The notoriously cruel and injudicious rule which permits one of the lay members of the commission to visit the asylums and tell the people they are insane, we believe to be needlessly severe and foolish, and the regulations prescribed for the management of private asylums, with the alternative of a withdrawal of the license, are a distinct infringement upon personal rights. Several of my friends who have private institutions have meekly submitted rather than suffer, and the instances of professional discourtesy which a large number of physicians endure call for some abridgment of power of those gentlemen who make their own laws. I am loath to believe that the medical member who is in the minority is responsible for the obnoxious methods of his associates; but as a physician he is certainly responsible for allowing himself to be used to injure and insult a large number of his professional brethren.

It is hoped that some action will be taken before the present Legislature adjourns, and physicians generally are invited to forward their grievances to the undersigned.

Allan McLane Hamilton, M.D.

20 East Twenty-ninth Street, March 2., 1892.

THE COUNTRY WAY OF DOING IT.

To the Editor of the Medical Record.

Sir: In the Medical Record of February 20, 1892, on page 222, will be found a clipping from the *College and Clinical Record*, which represents Professor Parvin as advocating the use of the ordinary male catheter instead of the female for catheterization of the female bladder.

It seems to me that owing to the wide circulation given this by the Record, and the well known ability of Professor Parvin as an author and teacher, it ought not go unchallenged.

Many readers of the Record are, like myself, country doctors. They are especially interested in this subject inasmuch as their female patients are, as a rule, very sensitive about any exposure of these parts, and are very much afraid of being hurt.

If by "ordinary male catheter" Professor Parvin means the one ordinarily carried by a physician in his pocket case, he means the silver catheter, which of course is hard and is more difficult to pass than the silver or glass female catheter. If he means the soft rubber male catheter, it is more difficult to pass into the female bladder than is a hard catheter. The catheter known as the "Glasgow Linen," with short blunt point, is as easily passed, perhaps, as the silver or glass one, but not any easier. Then why change the catheter or carry an additional one or more?

In an active practice of over ten years I have been compelled to catheterize many women. I have tried all kinds of catheters and find the ordinary silver or glass female catheter the easiest for both patient and physician. The physician who needs to expose a female in order to catheterize her with any style of catheter has had very poor college training or should change his occupation. The reader would infer from the clipping referred to that Professor Parvin introduces a vessel into the bed to receive the contents of the bladder about to be catheterized. If such is a true inference the country doctor can give his city friend a point worth knowing.

The countryman, who of course carries "hayseed in his hair," carries also in his pocket-case, his buggy-case, or his hand-satchel, about four feet of small gum tubing. One end of this he applies to the catheter before introducing it. The other end he places in a vessel under the bed. In this way he can catheterize his female patient "without soiling the clothes or necessitating any exposure of the patient." It is better than any form of catheter alone, for he runs no risk of soiling patient or clothes by accident, or awkwardness on the part of either his patient or himself.

Yours truly,

Spencer M. Free, M.D.

New Instruments.

A NEW BABY INCUBATOR.

By EDWARD J. BROWN, M.D.,

Minneapolis, Minn.

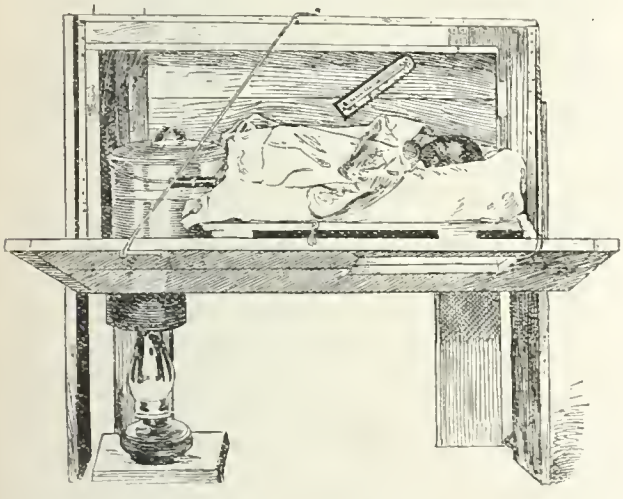
I have lately had an experience in rearing an immature infant which may be of interest to the profession. The child, a healthy and well formed male, was born September

[illegible] gestation

the first month, and every three hours the second month, fed and changed, and with a daily bath required absolutely no further attention. For two weeks he was fed with breast milk from a spoon and afterwards was able to nurse. In six weeks he had doubled his weight, weighing 9 pounds. When he left the incubator at the end of eight weeks he weighed 10¾ pounds and measured twenty-two inches, and now, at the end of five months, weighs 17½ pounds and measures twenty six inches.

The temperature of the interior of the box was maintained at from 86° to 90° F. during the first month, and gradually lowered to 80° F. during the second. A slight coryza lasting a few days was the only noteworthy event of the whole two months.

The complete incubator consists of a packing box 33 inches long, 21 inches high, and 12 inches wide, inside measure; a false bottom upon which the mattress is placed, and under which the fresh air is admitted, through an opening 4 × 10 inches; a false top with opening over the child's head for escape of warm air; a three-gallon pail of water, and hot air and smoke flues. The bottom of the box has a hole cut in it to admit the pail, which rests upon a piece of sheet iron under which a lamp or gas-jet is placed. The sheet iron, one foot square, is nailed to the box. The heat from the lamp is concentrated under the pail by a six-inch section of stove-pipe, and the fumes conducted by a two-inch smoke-flue up through the four-inch warm air-escape, thus producing a constant and sufficient current of air through the incubator. The front of the box opens on hinges at the bottom and has a large glass window which affords a view of the child and the thermometer which hangs on the back wall. Filling the pail with water at about 120° F., an ordinary bracket-



lamp, with very slight attention, will maintain a uniform temperature 15° to 25° F. higher than that of the room. By covering the box with building paper and throwing a folded quilt over it, the temperature may be maintained with less heat from the lamp and consequently with a lower temperature of the pail of water. The pail may be fitted with a tight cover or with openings for evaporation if more moisture be desired in the air. The sheet iron need never be heated to such a point as to be objectionable.

It is easy to suggest improvements, but this incubator was made in an emergency, and I present it to the profession, not as an ideal, but as a simple, practical, labor and life saving device, which any clod-hopper ought to be able to construct in a few hours, and from such materials as are always at hand.

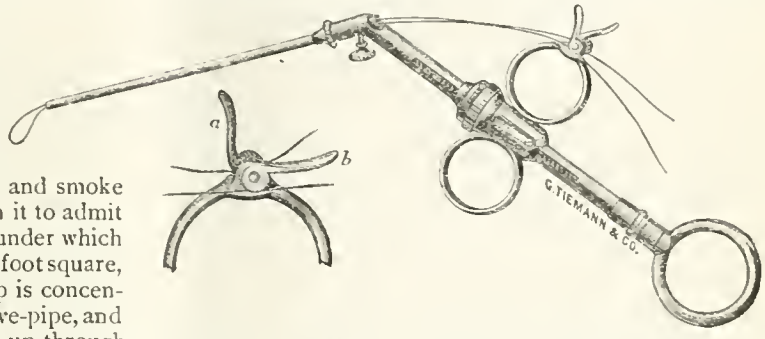
In conclusion, I will suggest that such an apparatus as I have described might be of great use also in cases of disease of the respiratory organs in weak infants where favorable conditions of temperature and freedom from draughts could not otherwise easily be secured.

Minneapolis, February 3, 1892.

NEW METHOD OF FASTENING THE WIRE IN NASAL SNARES.

By E. L. OATMAN, M.D.,
NYACK, N. Y.

In the best of nasal snares the manner of fastening the ends of the wire is oftentimes a source of annoyance and delay, especially so when in the midst of an operation it becomes necessary to shorten the loop. My attempted improvement consists in catching the wire between an eccentric wheel, with an attached lever, and the flattened upper surface of the carriage, the opposing surfaces being roughened to prevent slipping. The modification was adapted to Hooper's snare and ecraseur, but it is also



applicable to any other instrument similarly constructed. The wire should be accurately placed and the lever pressed down with only moderate force.

In testing the instrument constructed for me by Tiemann & Co. the wire invariably broke before slipping from the "catch."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 9, 1892.

	Cases.	Deaths.
Typhus fever	7	2
Typhoid fever	11	5
Scarlet fever	250	36
Cerebro-spinal meningitis	6	7
Measles	502	32
Diphtheria	143	29
Small-pox	16	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0
Mumps	0	0

Warming Railway Carriages.—The following item from *The Lancet* of recent date reads as though it had been written a quarter of a century ago instead of last month. It is amusing, but at the same time encouraging, for it gives evidence of real progress. It says, concerning the Midland Railway Company, that "quite recently their characteristic zeal for any change that tends to increase the amenities of travel has introduced what promises to prove a useful and economical method of carriage warming. Since the new year trains have been running between St. Pancras and Bradford in which a system of heating by means of pipes in direct communication with the engine has been carried out, so far with complete success. According to this arrangement the pipes can be filled either with steam or with hot water. A moderate average temperature can thus be maintained without trouble. When we contrast this apparently easy and obviously convenient process with the elementary and laborious method until now in common use, and remember that it has been employed in domestic heating for

many years past, we can only feel the more surprised that it has not sooner been applied to the purpose above mentioned. It is to be hoped that we shall, as time goes on, have such confirmation of its successful use as will ensure its general adoption by railway authorities. The advantage obviously resulting to the health as well as the comfort of travellers from the assured maintenance of an equable temperature in each carriage need not be insisted on."

Microcephalus.—Dr. John A. Wyeth, of New York, writes: "As a further contribution to the history of a case of microcephalus, which I operated upon and reported in your journal about a year ago, I wish to state that I have two letters from the mother of the child dated October 30, 1891, and January 5, 1892, in which she says, 'He pulls up by the chairs, goes the whole length of the bath tub by holding on the side; is fat, eats well, tries to talk, says "bye-bye" and waves his hand like other babies. We have taught him several little tricks which he remembers well. The only trouble I can see is his slapping his head with his hands. When he gets angry he just pounds it. His left eye is a little turned when he looks up, otherwise he is doing well; sleeps beautifully. I feel really encouraged over him.' I feel that I am justified in considering the improvement as wonderful in this case."

Insanity in Paris.—From a report recently issued by Dr. Paul Garnier, it appears that the number of cases of insanity registered at the Paris Prefecture of Police in 1888 was 4,449 as against 3,080 in 1872, being an increase of nearly one-third. The total number of insane persons known to the authorities in Paris for the seventeen years ending January 1, 1889, was 62,572, of whom 34,882 were men, and 27,770 women.

A Psychiatrico-Criminological Museum is to be established at the University of Turin, under the direction of Professor Cesare Lombroso. It is proposed to form a collection illustrating as far as possible the mental and physical characteristics of lunatics and criminals, and supplying the necessary materials for the scientific study of the various types of mental or moral abnormality. Among the objects collected will be skulls, skeletons, and brains of criminals, pathological specimens from the bodies of criminals and the insane, instruments for the study of insanity and for craniometry, plans of prisons and lunatic asylums, autographs of lunatics and criminals, materials for the geographical distribution and statistics of crime, etc.

Hazing in a Hospital.—A story appeared in a recent issue of an Edinburgh paper to the effect that for several years the various batches of residents at the Royal Infirmary had fallen into the habit of practical joking, the writer asserting that "lately these performances have been getting rougher and more personal. The latest little pleasantry was a process of blistering. The victim was set upon by five or six men, against whom, of course, he had no chance, although it is said he struggled gamely, knocking one of his assailants down before he fainted. Other men have been bathed." The *British Medical Journal* was disposed to assume that the story was invented, or, at the least, very greatly embellished by the reporter, but upon making inquiries found that the story was true. "The gentleman subjected to this cowardly assault was taking temporary duty during the illness of one of the resident physicians. After having been subjected to one or more baths he became unconscious, and it is charitably supposed that the mustard was applied as a restorative."

Chronic Cystitis.—Dr. Tyson (*The Practitioner*, February, 1892) says the successful treatment of chronic cystitis is a difficult task for three evident reasons: 1. The constant presence in the bladder of the urine with its irritating qualities. 2. The difficulty of getting remedies to reach the inflamed surface. 3. The pent up inflammatory products, which in their decomposition often make the urine still more irritating by exciting in it ammoniacal changes. The irritating qualities may be diminished by diluents. The second indication is met by drugs internally, or by injections of medicated fluid. Sandalwood oil has been found useful, and is about the only remedy which the author has found to have a direct beneficial effect upon the mucous membrane of the bladder. Benzoic and boric acids have both been found to exert an antiseptic effect on the urine when given in five grain doses, and increased to ten. Where a foul odor is present a dilute solution of bichloride, beginning with one to twenty-five thousand and gradually increased in strength, is used as an injection into the bladder with good results. That an absolute and total cure is ever obtained in chronic cystitis is regarded by the author as exceedingly doubtful.

First Aid to the Injured in the French Army.—The French Minister of War has issued an order that henceforth every officer and every man in the French Army shall, when on active service, carry on his person material for a first dressing in case of his being wounded.

Vesical Tuberculosis.—Dr. Petit (*Annales de la Policlinique*, January, 1892), has found very beneficial effects in tuberculosis of the bladder from the combined internal and local employment of iodoform. Ten centigrammes are given in pill form by the mouth, and the bladder is injected with a teaspoonful of the following, suspended in 150 grammes of tepid water, to which is added ten drops of laudanum:

℞. Iodoform	.....	gm. 20.
Glycerine	.....	gm. 10.
Aq. dest	.....	gm. 6.
Gum tragacanth	.....	ctgr. 0.25.

Substances Incompatible with Antipyrin.—According to the *Pharm. Centralblatt* the following substances precipitate antipyrin from aqueous solution: 1, Phenic acid in concentrated solution; 2, tannin and tannic acid preparations; 3, tincture of iodine; 4, chlorides or mercury. The following decompose antipyrin when triturated with it in a dry state: 1, calomel, forming a toxic combination; 2, beta naphthol; 3, chloral, which forms an oleaginous liquid; 4, bicarbonate of soda (an acetic ether odor is given off); 5, salicylate of soda, also forming an oleaginous liquid; 6, the salts of quinine and caffeine, of which the solubility is increased by antipyrin.

The Treatment of Exophthalmic Goitre.—Dr. Fergusson has secured good effects from the use of strophanthus in the treatment of exophthalmic goitre. In nine cases in which he has used it the almost immediate disappearance of the cardiac symptoms permit the patients to renew their usual occupations. The pulse falls from 150 and over to 75 or 85. At the same time there is diminution in the exophthalmos and in the size of the thyroid gland on condition that the latter has not become fibrous from the long duration of the affection. The author does not affirm that the cure is positive, but he maintains that the amelioration is very considerable. Eight to ten-drop doses three times daily are recommended. In some cases he has increased the dose to twenty and twenty-five drops.

Infection in Furunculosis.—Dr. Preto (*Riforma Medica*, January 27, 1892) has made some researches from which he concludes: 1. The infection produced by the staphylococcus pyogenes aureus does not become generalized if there is elimination by the kidneys and skin. 2. If the staphylococcus is eliminated by the kidney it has a vitality below the ordinary, without our being able to say why. 3. The organism rarely succumbs to a general infection. 4. The chief therapeutic indication in such a case should be to increase by all possible means diaphoresis and diuresis. 5. Isolation of those affected, disinfection of the places in which they have remained and the clothing which they have worn is necessary to avoid contagion.

PRESENT PROBLEMS IN EVOLUTION AND HEREDITY.

THE CARTWRIGHT LECTURES OF 1892.

(Continued from page 261.)

BY HENRY FAIRFIELD OSBORN, SC.D.,

DA COSTA PROFESSOR OF BIOLOGY IN COLUMBIA COLLEGE, NEW YORK.

LECTURE III.

HEREDITY AND THE GERM-CELLS.

ACCORDING to the general law[1] the germ-cell was considered as matter potentially alive and having within itself the tendency to assume a definite living form in course of individual development. The nucleus must be extraordinarily complex, for it contains within itself not only the tendencies of the present type, but of past types far distant. The supposition of a vast number of germs of structure is required by the phenomena of heredity; Nägeli has demonstrated that even in so minute a space as $\frac{1}{1000}$ cub. millimetre, 400,000,000 micellæ must be present.

The study of heredity will ultimately centre around the structure and functions of the germ-cells. The precise researches of Galton show that the external facts of heredity, questions of averages and of probabilities, of paternal and maternal contributions to the offspring, are capable of being reduced to an exact science in which mathematical calculations will enable us to forecast the characteristics of the coming generation.

There will still remain, however, a large residuum of facts which will present themselves to a mathematician like Galton as chance or inexact, such as: the physiological conditions of reversion; the causes of prepotency, by which the maternal or the paternal characteristics prevail in parts or in the entire structure of the offspring; the material basis of latent heritage upon which reversion depends, and which compels us to hypothecate either an unused hereditary substance or a return to an older disposition of the forces in this substance; the nature and determination of sex. These apparently chance phenomena must also be due to certain fixed laws, and by far the most promising routes to discovery have already been taken by Van Beneden, the Hertwig brothers, Boveri, Maupas, and others.

They have attacked the problem of the relation of the germ-cells to heredity on every side, and by the most ingenious and novel methods, which are familiar enough in various branches of gross anatomical and physiological research, but seem almost out of the limits of application to minute microscopic objects. For example, the Hertwig brothers have ascertained the influences of various solutions of morphine and other drugs, of the alcohols, and of various degrees of temperature upon the ovum and spermatozoon during the conjugation period, with results which are highly suggestive of the causes of congenital malformations, anomalies, and double births. The Hertwigs and Boveri have succeeded in robbing ova of their nuclei and watching the results of the subsequent entrance of spermatozoa. In order to further test the relations of the nucleus to the remainder of the cell, Verworn has experimented along the same line with extirpations of every kind from the single cells of Infusoria. Of equal novelty are the recent studies of Maupas upon the multiplication and conjugation of the Infusoria, giving us a host of new ideas as to the cycle of life, the meaning of sex, and the origin of the sexual relation.

In all this research and in the future outlook there are two main questions:

1. *What is the hereditary substance?* What is the material basis of heredity, which spreads from the fertilized ovums to every cell in the body, conveying its ancestral characteristics? Is there any substance corresponding to the hypothetical idioplasm of Nägeli?

2. *What are its regulating and distributing forces?* How is the hereditary substance divided and distributed? How far is it active or passive?

I may say at the outset that the idioplasm of Nägeli, a purely ideal element of protoplasm which he conceived of as permeating all the tissues of the body as the vehicle of heredity, has been apparently materialized in the *chromatin* or highly coloring materials in the centre of the nucleus. This rests upon the demonstration by Van Beneden and others that chromatin is found not only in all active cells, but is a conspicuous element in both the ovum and spermatozoon during all the phenomena attending conjugation.

Secondly, that while the chromatin is apparently passive, it is played upon by forces resident in the clear surrounding protoplasm of the nucleus, but chiefly by the extra-nuclear *archoplasm*, which seems to constitute the dynamic and mechanical factor in each cell. This, unlike the chromatin, only comes into view when there is unusual activity, as during cell-division, and is not evident (with our present histological technique), at least, when the cell is arrested by reagents in the ordinary stages of metabolism.

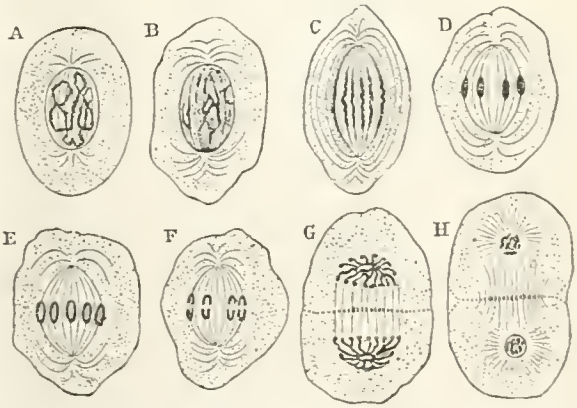

FIG. 7.—TYPICAL CELL DIVISION, SHOWING THE DISTRIBUTION OF CHROMATIN. (From Parker, after Carnoy.) A–C, Arrangement of the chromatin in threads; D–E, Formation of the chromatin rods and loops; F, Splitting of the loops; G–H, Retraction of the chromatin into the two daughter-cells.

The Distribution of Hereditary Substance.—I may first review some of the well-known phenomena attending the distribution of the chromatin substance to the tissues.

I have borrowed from Parker figures by Carnoy to illustrate the resting and active stages of the cell, and from Watase, a Japanese student of Clark University, figures representing the high differentiation of the cell-contents during division (Figs. 8, 9). They bring out the active and passive elements of the typical cell.

The phenomena of karyokinesis which attend the division and distribution of the hereditary substance through-

[1] See Huxley, Article Evolution, Enc. Britannica, p. 746.

out the whole course of embryonic and adult development are well illustrated in Carnoy's figures (Fig. 7). First we have the quiescent period, in which the chromatin presents the appearance of a coiled, tangled thread; surrounding this is the clear nucleoplasm (or achromatin) bounded by the nuclear membrane; the extra nuclear substance, or cytoplasm, is apparently undifferentiated. As soon as cell division sets in, however, radiating lines are seen in the cytoplasm above and below the nucleus, these are called the archoplasmic filaments by Boveri, since they proceed from what is now believed to be the dynamic element, the archoplasm (Fig. 8). As the activity becomes more intense the filaments are seen to diverge from a centre—the archoplasmic *centrosome*—which lies just without the nucleus at either pole; this radial display of cell-forces suggested the term "asters" to Fol, and "spheres attractive" to Van Beneden. The behavior of the chromatin, or hereditary substance, under these archoplasmic forces, is beautifully shown in Carnoy's diagrams (Fig. 7). First, the nuclear wall breaks up, then the chromatin coil unfolds into lines of vertical striation which become thread-like, hence the term mitosis, and

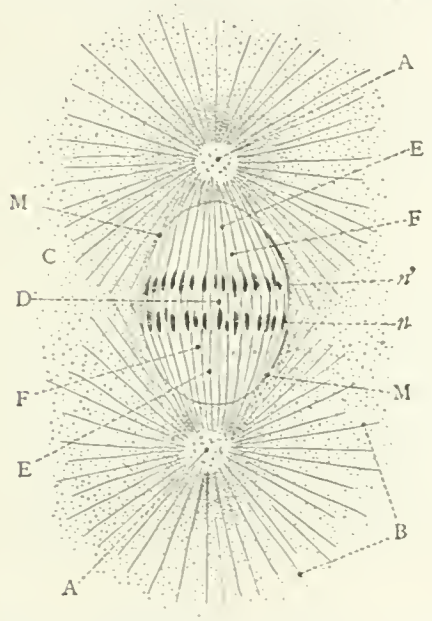

Fig. 8.—Before Division. Differentiation of the Cytoplasm and Nucleus during Cell Division of a Squid Embryo, Loligo. (After Watase.) M, The nuclear membrane; F, Achromatin or nucleoplasm; C, Cytoplasm, or protoplasm outside of the nucleus; A-A, The two centrosomes of archoplasm; E, Extra nuclear archoplasmic filaments; E, Intra-nuclear archoplasmic filaments attached to *n*, *n'*, the chromatin rods.

then more compact, until finally a number of distinct vertical rods, chromatin rods, or *chromasomes* are found.

A remarkable and significant fact may be noted here, that the number of chromosomes varies in the cells of different species, and even in the cells of different varieties (as in the thread-worm of the horse—*Ascaris megalocephala*), but is constant in all the cells of the same variety through all stages; thus the same number of chromosomes appears in the first segmentation of the fertilized ovum as in the subsequent cell division in the tissues.

Carnoy next indicates the vertical splitting of each rod into a loop or link preceding the horizontal splitting; thus we may conceive of a thorough redistribution of the chromatin before it passes into the daughter-cells. The split loops are each retracted toward a centrosome, suggesting to some authors a contractile power in the archoplasmic filaments; each chromosome being apparently withdrawn by a single filament. But as the chromasomes separate, the filaments also appear between them, and are variously termed "interzonal," "verbindungs fäden," "filaments réunissant;" there is, therefore, some difference of opinion as to what the mechanics of the chromosome divisions really are. The chromatin is now retracted into two coiled threads, each the centre of the daughter-nucleus with a single centrosome beside it. But as the line of cleavage is drawn between the two cells (Fig. 9), the single centrosome in each cell divides so that each daughter cell is now complete with its chromatin coil and two archoplasmic centrosomes. This process has been beautifully described by Watase.[1]

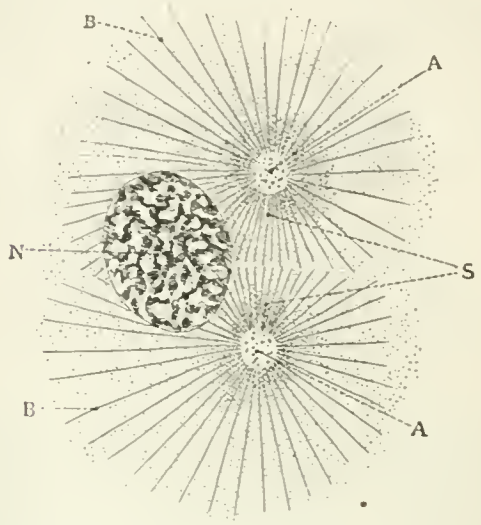

Fig. 9.—After Division. Interior of a Daughter-cell in the Squid. (After Watase.) Division has just taken place and the daughter-nucleus, N, shows the chromatin coil. The daughter centrosome is just forming two new centrosomes, A-A, by direct division.

It thus appears that both the chromatin and archoplasm are permanent elements of the cell, such as we formerly considered the nucleus; the apparently passive chromatin is divided with great precision by the active archoplasm, then the archoplasm simply splits in two to resume the cleavage function.

Fertilization—the Union of Hereditary Substances.—Before looking at the host of questions which fertilization suggests, let us review a few of the well-known phenomena preparatory to the union of the germ cells, in order to give greater emphasis to the importance of recent discoveries.

First, the ovum is a single cell, the typical structure of which, with its nucleus and cytoplasm, is generally obscured by a quantity of food-material, surrounded by a rather dense cell-wall. The ovum is said to be ripened or "matured" for the reception of the spermatozoon, by the extrusion of two small "polar bodies," containing both chromatin and hyaline protoplasm, and separating off by karyokinetic division. After maturation is complete, a single spermatozoon normally penetrates; then a reaction immediately sets in in the cell-wall of the ovum which prevents other spermatozoa from entering. The head of the spermatozoon and the nucleus of the ovum now fuse together to form a single nucleus, which it is obvious contains the hereditary substance of two individuals. This is the starting point of the segmentation or distribution process above described, and it follows that the fertilized ovum at this stage must contain its typical complement of chromatin, archoplasm, etc., for the whole course of growth to the adult.

How shall we connect these phenomena of fertilization with the facts of heredity? The most suggestive enigma in connection with the fertilization process has been *the meaning of the two polar bodies*, especially since Van Beneden demonstrated that they contained chromatin? For twenty-five years speculation has been rife as to why the ovum should extrude a portion of its substance in two small cells; why not in one cell? why not in a larger number? Thanks to the intense curiosity which these polar bodies have aroused, and to the great variety of explanations which have been offered for them, we have

[1] See Marine Biological Laboratory Lectures, 1889. Boston: Ginn & Co.

arrived to-day at a solution which links the higher animals with the lower, breaks down the supposed barrier between the sexes, and accords with the main external facts of heredity. It seems to me best to disregard the order of discovery, and to state the facts in the most direct way. First, a few words as to the speculations upon the meaning of the polar bodies.

The early views of fertilization[1] were naturally based upon the apparent significance of this process in the human species, in which the sexes are sharply distinguished from each other in their entire structure, and the reproductive cells are also widely differentiated in form, the ovum large and passive, the spermatozoon small and active. The readiest induction was to regard these elements as representing distinct physiological principles, corresponding to the essential sexual characteristics—in short, as male and female cells, the former vitalizing and rejuvenating the latter. Thus one of the earliest definite "polar-body" theories was that the ovum was hermaphrodite, containing both male and female principles, and that it was necessary to get rid of the male substance before the spermatozoon could enter.

As Von Siebold and Leuckart had demonstrated that some ova reproduce parthenogenetically, that is without fertilization by spermatozoa, Weismann turned to such forms for the solution of this problem, and was surprised to find that parthenogetic ova only extrude one polar body; this led him to attach one meaning to the first polar body, and another meaning to the second, which he viewed as designed to reduce the hereditary substance in the ovum without regard to sex. Thus both this and the older theory conveyed alike the idea of *reduction*, but with an entirely different supposition as to the nature of the material reduced or eliminated.

Maupas on Conjugation among the Infusoria.[2]—Among the newer researches which throw light upon this old problem, those of Maupas are certainly the most brilliant. After a most exact and arduous research, extending over several years, he collected his results in two memoirs, published in 1889 and 1890.

His experiments were first directed upon the laws of direct multiplication by fission, which revealed a complete cycle of life in the single celled Infusoria and showed that after a long period this mode of reproduction becomes less vigorous, then declines, and finally ceases altogether unless the stock is rejuvenated by conjugation of individuals from different broods. In other words, these broods of minute organisms grow old and die unless they are enabled to fertilize each other by an exchange of hereditary substance altogether analogous to that observed in the higher multicellular organisms.

The cultures were made in a drop of water upon a slide, and feeding was adapted either to the herbivorous or carnivorous habits of the species. Under these conditions it was found that the rate of fission or direct multiplication varied directly with the temperature and food, rising in some species (*Glaucoma scintillans*) to five bipartitions daily. With the optimum of conditions this rate, if sustained for thirty-eight days, would produce from a single individual a mass of protoplasm equivalent to the volume of the sun. This rate is, however, found to be steady for a time, and then the offspring decline into "senescence," in which they appear at times only one-fourth the original size, with reduced buccal wreaths and degenerate nuclear apparatus. Finally, even under the most favorable conditions of environment, death ensues. This is reached sooner in some species than in others; *Stylonichia pustulata* survives three hundred and sixteen generations or fissions, while *Leucophrys patula* persists to six hundred and sixty generations.

Not so where conjugation is brought about by mingling the offspring of different broods in the same fluid, as in the natural state. Maupas soon discovered that exhaustion of food would induce conjugation between members of mixed broods. He thus could watch every feature of the conjugation process, and determine all the

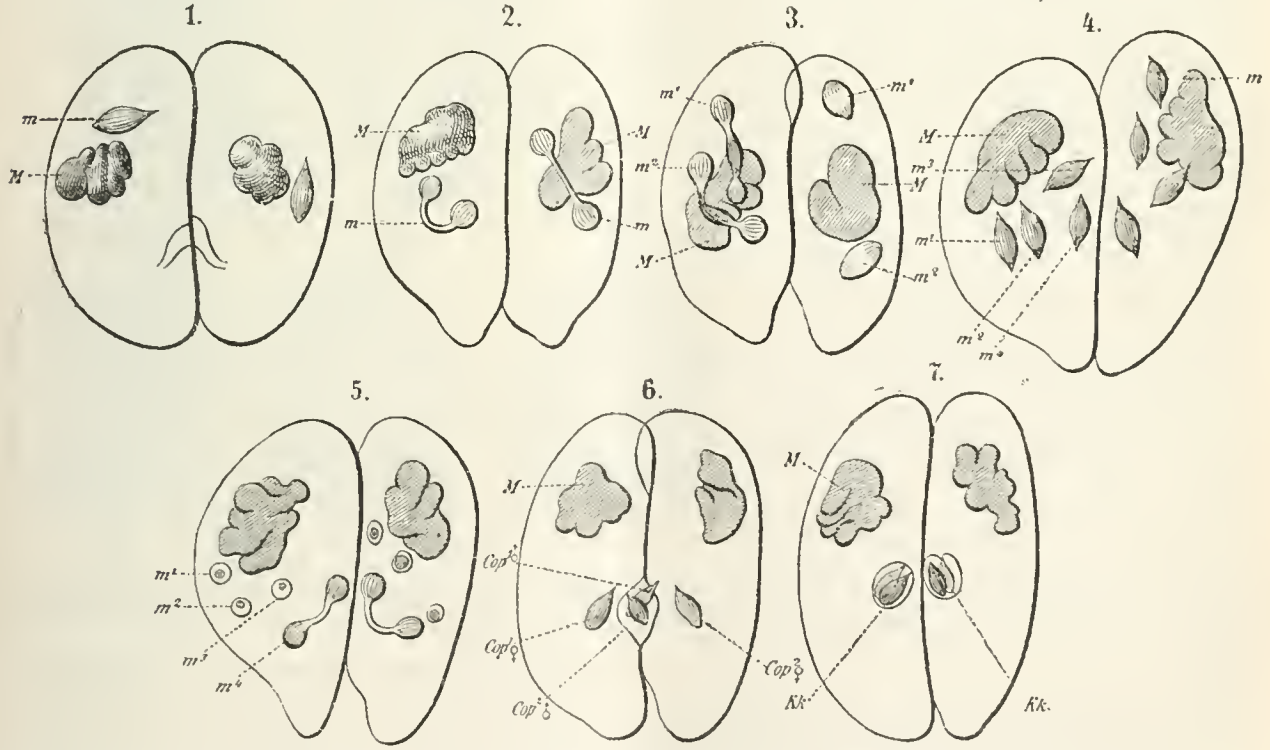

Fig. 10.—The Conjugation of Infusoria. (From Weismann, after Maupas.) 1, Two infusoria uniting; *M*, meganucleus; *m*, micronucleus; 2–5, Successive divisions of micronuclei; 6, The migration of one of the persisting micronuclei from each infusorian into the other; 7, Union of the interchanged micronuclei.

phases in the cycle of life. These differed, as in the longevity of the species. In *Stylonichia*, for example, "immaturity" extended over the first one hundred bipartitions; "puberty," or the earliest phase favorable to conjugation, set in with the one hundred and thirtieth bipartition; "eugamy," or the most favorable conjugation phase, extended to the one hundred and seventieth; then "senescence" set in, characterized by a sexual hyperæs-

[1] See also the introduction of Weismann's last essay, Amphimixis.

[2] Sur la multiplication des Infusoires Ciliés, Archiv. de Zoologie expérimentale, Sér. 2, vol. vi., pp. 165–273; Le Rajeunissement Haryogamique chez les Ciliés, vol. vii., pp. 149–517. See also Cartoy, Quart. Journ. Microscop. Science, December, 1891.

thesia in which conjugation was void of result or rejuvenescence, owing apparently to the destruction of the essential nuclear apparatus.

Conjugation begins with the approach of two individuals, and adhesion by their oral surfaces. There is no fusion, but an immediate transformation in the cell contents of each individual sets in, concluding with an interchange of nuclear substance. In each cell Maupas distinguishes between the (*M*) *meganucleus* (Fig. 10, the macronucleus, nucleus, endoplast of authors), which presides over nutrition and growth and divides by constriction, and the (*m*) *micronucleus* (paranucleus, nucleolus, of authors), which presides over the preservation of the species. The latter contains chromatin; it is the seat of rejuvenescence, the basis of heredity, it divides by mitosis, showing all the typical stages of karyokinesis excepting the loss of the cell membrane.

The transformation in each of these copulating cells first affects the centres of hereditary substance, viz., the micronuclei; they divide three times; thus the micronuclear substance is reduced to one-fourth of its original bulk. It is contained in two surviving micronuclei (the others being absorbed or eliminated), one of which migrates into the adjoining cell; the other remains stationary. This migration is followed by a fusion of the migrant and stationary micronuclei: this fusion effects a complete interchange of hereditary substance, after which the two infusoria separate and enter upon a new life cycle. Meanwhile the meganucleus breaks up and is reconstituted in each fertilized cell.

Maupas gathers from these interesting phenomena additional proof that the chromatin of all cells bears the inherited characteristics and that the cytoplasm and nucleoplasm, or achromatin, is the dynamic agent, because the micronuclei bearing the chromatin are the only structures which are permanent and persistent, all the other structures—nucleoplasm, archoplasm, etc.—being replaced and renewed. The reduction of the chromatin is purely quantitative, the eliminated and fertilizing micronuclei being exactly equivalent; after the chromatin has been quartered the cell becomes incapable of further activity until it is reinforced by chromatin from the copulating cell.

No Distinction between the Sexes in Heredity.—The three laws which underlie these phenomena are: 1. That fertilization consists in the union of the hereditary substance of two individuals. 2. That before union the hereditary substance in each is greatly reduced. 3. That there is no line between male and female, the conjugating cells are simply in a similar physiological condition wherein a mingling of hereditary characteristics affords a new lease of life. As Maupas says:

"Les différences appelées sexuelles portent sur des faits et des phénomènes purement accessoires de la fécondation. La fécondation consiste uniquement dans la réunion et la copulation de deux noyaux semblables et équivalents, mais provenus de deux cellules distinctes."

In this conclusion as to the secondary and superficial, rather than fundamental, difference between the two sexes, Maupas simply confirms the views of Strassburger, the botanist, Hensen, B. and O. Hertwig, Weismann, and others, namely, that sex has evolved from the necessity of cell conjugation; that even in the higher forms the cells born by the two sexes are absolutely neutral so far as sex is concerned, the wide difference of form of the germ cells is a result of physiological division of labor—the mass and yolk of the ovum having been differentiated to support the early stages of development while the spermatozoon has dispensed with all these accessories and acquired an active vibratile form for its function of reaching and penetrating the ovum. The evidence of the Infusoria is paralleled among some of the plants, in which conjugation between entirely similar cells is observed.

The causes finally determining sex may come surprisingly late in development, and according to the investigations of Düsing and the experiments of Yung[1] and of Giron are directly related to nutrition. High feeding favors an increase of the percentage of females, while, conversely, low feeding increases the males. In Yung's experiments with tadpoles the following results were obtained:

	Females.	Males.
Normal percentage	57	43
High nutrition	92	8

Geddes expresses this principle in physiological terms of metabolism, that anabolic (constructive) conditions produce females, while katabolic (destructive) conditions produce males.

I think we may now safely eliminate the factor of sex from our calculations upon the problem of heredity, and thus rid ourselves of one of the oldest and most widespread fallacies. We shall thus, in using the terms "paternal" and "maternal" imply merely the distinction between two lines of family descent.

The Theory of Reduction.—This leads us back to the significance of the polar bodies. Van Beneden's discovery that these bodies contained chromatin led gradually to the view that they were not fragments of the ova, but represented minute, morphologically complete cells. Bütschli showed that they were given off independently of, and prior to, the contact of the spermatozoon, and, finding in the leeches that the first polar body subdivides to form two bodies, he considered them as formed by true cell division, and containing both nucleoplasm and chromatin. Giard independently reached a similar opinion, assigning an atavistic meaning to the polar cells. Whitman, in 1878, advanced the idea that they represented vestiges of the primitive mode of reproduction by fission, while Mark described them as "abortive ova."

At this point speculation subsided until it was revived by Weismann's attempt to connect these bodies with his

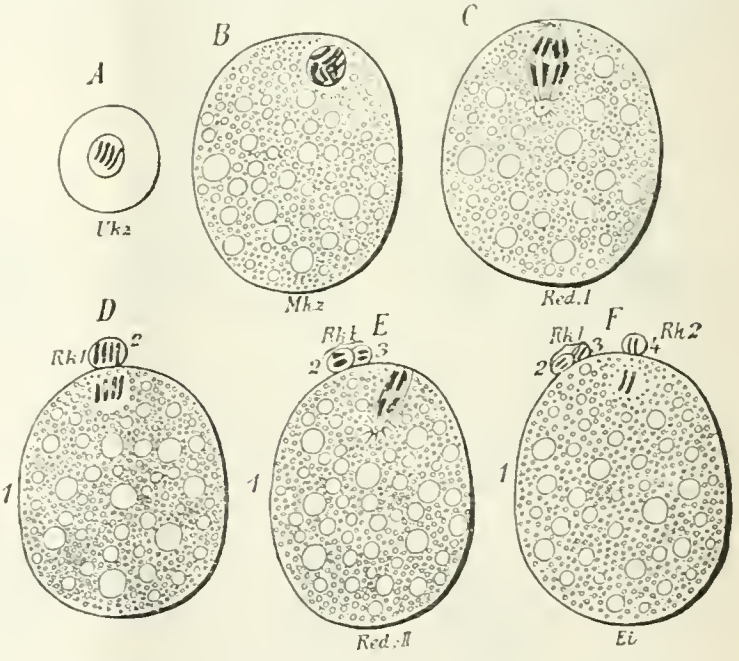

FIG. 11.—THE MATURATION OF OVA, OR FORMATION OF POLAR BODIES IN ASCARIS. (From Weismann after Hertwig.) A, original germ-cell in embryonic germ-layer—4 chromatin rods; B, Ovum mother-cell—8 rods; C-D, First polar body extruded; E, Splitting of first polar body. Ovum still contains 4 rods; F, Second polar body extruded. Ovum mature with 2 rods.

[1] See Geddes and Thomson: The Evolution of Sex, 1891; also, Düsing: Die Regulierung des Geschlechtsverhältnisses bei d. Vermehrung der Menschen, Tiere und Pflanzen, Jen. Zeit. f. Natur, Bd. 17, 1884.

theory of heredity,[1] already referred to. The whole question is clearly given in R. Hertwig's masterly memoir upon Ovo and Spermatogenesis in the Nematodes.[2] Taking advantage of Boveri's discoveries in staining technique, and stimulated by Weismann's prediction that spermatozoa would also be found to extrude polar bodies, this author examined all stages in the peculiarly favorable germ cells of the thread-worm of the horse (*Ascaris megalocephala*).

He made the surprising discovery that ova and spermatozoa are formed in a substantially similar manner by repeated divisions, the single difference being that the last products of division among the sperm cells are effective spermatozoa, capable of development in fertilization, while the last products of division in the ovary are, first, the true ova, and second, the abortive ova (polar cells) incapable of development. In both ova and spermatozoa the nucleus contains but one-half the chromatin which a typical nucleus contains; in the case of *A. megalocephala* each of the germ-cells contains but two chromasomes while the normal body-cells contain four. The manner in which this maturation of the germ-cells for conjugation is brought about is beautifully shown in these diagrams, taken from Weismann's essay, "Amphimixis." You observe that the number of chromasomes in the primary germ-cells is four (Fig. 12). Then are formed by subdivision the ovum and sperm "mother cells," in which the chromatin substance is doubled, so that we observe eight chromasomes. The mother-cells then divide and the chromatin is reduced to four rods, a second division rapidly follows whereby the chromatin is reduced to two rods, or half the original quantity. These last divisions take place by karyokinesis, but, as Hertwig points out, they differ from typical karyokinesis in the fact that the divisions follow so rapidiy upon each other that the vesicular resting-period of the nucleus is omitted. Thus, he suggests, is prevented an over-accumulation of chromatin substance prior to the fusion of the ovum and sperm. It is evident that the polar-cells are rudimentary ova, which do not possess the yolk-mass, etc., essential to development, and are divided off at a very late stage, sometimes after the egg has left the ovary, but are in other respects analogous to the spermatozoa. The reason these polar-cells have not disappeared altogether in either plants or animals is that they originally possessed a deep physiological importance. As the first polar-cell subdivides and forms two, it follows that from both ovum and sperm mother-cells four daughter-cells are formed, each containing half the chromatin substance of a normal nucleus, in the ovary three of these daughter-cells abort and the fourth forms a true ovum; in the sperm-gland, however, all four daughter-cells form spermatozoa.

We may thus consider the polar-cell problem as in all probability settled; the whole process is probably an inheritance or survival of a primitive condition in which all four ova, like the four spermatozoa, were fully functional.

The Relation between the Chromatin and Heredity.—We have just seen that the last stages in the preparation of the ova and spermatozoa for conjugation result in halving the number of rods in the original germ-cells. Now, as Hertwig and Weismann point out, one point is still left in doubt. Why is the chromatin substance doubled in the mother-cells so that two successive subdivisions are necessary to reduce it to half the original quantity? Hertwig has not attempted to answer this question, as he prefers to wait for further research. Weismann, however, who is unfortunately cut off from research by failing eyesight, has offered a speculative solution to this problem which he trusts may guide future investigation.

This leads me to say a few words in regard to his conception of the relation of the chromatin to heredity. 1. His first premise is that in fertilization there is not a fusion of chromatin but that a certain independence is preserved between the maternal and paternal elements, based upon the observed fact that the two pairs of rods do not fuse but lie side by side, and upon the assumption that these pairs

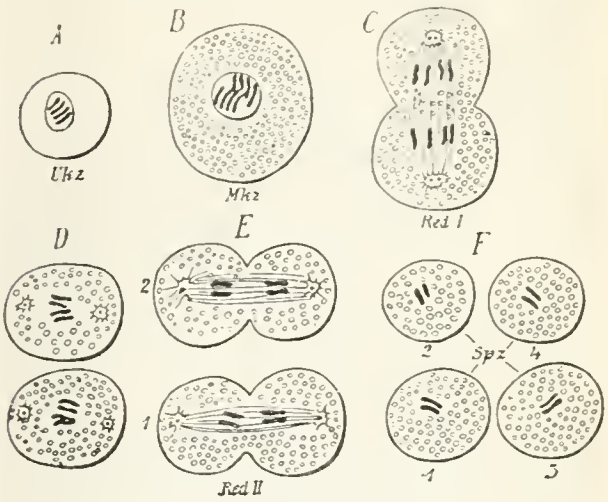

FIG. 12.—SPERMATOGENESIS IN ASCARIS. (From Weismann after Hertwig.) A, Original germ-cell—4 chromatin rods; B, Sperm mother-cell—8 rods; C-D, First daughter-cells with 4 rods each; E-F, Formation of second daughter-cells, or mature spermatozoa, with 2 rods each.

are kept distinct in each cell through all the subsequent stages of embryonic and adult development. If this is the case, the hereditary substance contributed by the father would remain separate from that contributed by the mother, throughout. 2. "Each of these pairs would be made up of the collective predispositions which are indispensable for the building up of an individual, but each possesses an individual character, for they are not entirely alike. I have called such units "ancestral plasms," and I conceive that they are contained in numbers in the chromatin of the mature germ-cells of living organisms, also that the older nuclear rods are made up of a certain number of these. . . . Obviously these units cannot become infinitely minute; however small they may be they must always retain a certain size. This follows from the extremely complicated structure which we must without any doubt ascribe to them." These units are not, however, ultimate, they are in turn extremely complex, and are composed of countless biological units of the kind conceived of by Nägeli and others. 3. The reduction of the chromatin only acquires a meaning when taken in connection with the above supposition of distinct ancestral plasms, and has no meaning if we accept Hertwig's view that there is a complete fusion of maternal and paternal germ-plasm. This meaning is that reduction in the maturation of germ cells is *sui generis*, it does not divide the ancestral plasms into two similar groups, but one daughter-cell receives one set of germ plasms or hereditary predispositions, and another daughter-cell receives another; reduction is thus differential. According to this view the four sperm and ovum daughter-cells would each contain a different set of ancestral plasms. 4. The fact that the chromatin substance is doubled in the sperm and ovum mother-cells, so that we observe double the number of rods characteristic of the species, is to be explained as an adaptation to the requirements of natural selection, for this doubling and subsequent double division render possible an infinite number of combinations (as many, in fact, as there are individuals) for Selection to operate upon.

This explanation of Weismann's is an example of his apotheosis of the theory of natural selection. Every process is made to suit this theory, which, as we have seen in the first and second lectures, is, in his opinion, the exclusive factor of evolution. But this very high degree of mingling and remingling of ancestral predispositions would be fatal to evolution, for after a combination favorable to survival had been established in one generation

[1] On the Number of Polar Bodies and their Significance in Heredity. 1887.

[2] Ei und Samenbildung bei Nematoden, Archiv. f. Mikr. Anat., Bd. 26, 1890.

it would be broken up into a new combination, perhaps unfavorable to survival, in the next generation. This entire essay upon "Amphimixis," or the theory of mingling of reduced hereditary substance, will, I believe, mark a turning point to decline in Weismann's influence as a biologist. His whole reasoning is now in a circle around natural selection.

The Meaning of Conjugation.—Weismann looks upon sexual reproduction as designed to mingle hereditary tendencies and to create individual differences whereby natural selection may form new species. It is evident that these combinations must be mainly fortuitous and productive of indefinite variation; but we have seen that evolution advances largely by the accumulation of definite variations, or those in which each successive generation exhibits the same tendencies to depart from the typical ancestral form in certain parts of the body, and that these tendencies stand out in relief among the diffused kaleidoscopic or fortuitous anomalies.

The fact, moreover, that variability and evolution by the accumulation of certain variations in successive generations is also observed in organisms which reproduce asexually, both among plants and animals, shows that we must look in another direction for the underlying cause or purpose of sexual reproduction. Weismann rightly combats the old idea of "vitalization" of the ovum by the spermatozoon, and it is perfectly evident from the researches of Maupas and Hertwig that the ovum may as accurately be said to vitalize the spermatozoon as the reverse. Fecundation is simply the approximation of two hereditary substances of distinct origin and their incorporation into a single nucleus. The action and reaction of these substances may be considered equal and mutual, so far as we now know.

The remarkably ingenious experiments of Hertwig and Boveri, above alluded to, strengthen this idea. Some years ago Weismann wrote: "If it were possible to introduce the female pronucleus of an egg into another egg of the same species, immediately after the transformation of the nucleus of the latter into the female pronucleus, it is very probable that the two nuclei would conjugate just as if a fertilizing sperm nucleus had penetrated. If this were so, the direct proof that egg-nucleus and sperm-nucleus are identical would be furnished." Boveri succeeded in accomplishing a similar feat by depriving an ovum of its nucleus and subsequently causing it to develop by admitting *two spermatozoa which fertilized each other and produced a complete individual.*

In opposing the vitalizing properties of the sperm, Weismann, however, went further, and advocated the view that there is nothing in the nature of vitalization or "rejuvenescence" in conjugation—that, given proper environment, protoplasm is immortal, and runs upon a course of undiminished activity. This we have seen is not the case in the infusoria, and, as recently remarked by Hartog, there is only one class of organisms which, according to our present knowledge, are completely agamous and immortal—namely, the Monadina. It may in future appear that even in the monads there is a cycle for the development in which conjugation plays its part.

Maupas's experiments seem to establish the primitive, and therefore the true, interpretation of the purpose of conjugation as well as of sex, the latter being a consequence of the former, namely, that after a long period of direct subdivision of hereditary material from a single individual, a limit is reached beyond which the forces of heredity are not reproduced in their original intensity unless combined with another set of similar forces of different origin. This combination restores the original intensity. It is objected to this that two sets of feeble forces cannot constitute one vigorous force, but this is met by the observed fact that such union does start a new life cycle, and is therefore rejuvenescent. We may regard this as the fundamental meaning of conjugation and the production of variations as entirely secondary.

The Distribution of the Chromatin.—We have now reviewed some of the main phenomena of fertilization; there still remains the relation of the hereditary substance to the future development of the individual. There is, first, the astonishing fact that, as the chromatin goes on dividing, its mass or volume remains apparently undiminished; that is, there is apparently as much chromatin in one of the many million active cells of the body as in the original fertilized ovum, and it is still an enigma as to the nature of this chromatin and its functions. Then there is the problem of the maternal and paternal elements in each cell; do they lie side by side or are they fused?

In plants De Vries[1] and others believe that all or by far the greater number of cells in the plant body contain the total hereditary characters of the species in a latent condition. Kölliker[2] has fully discussed this question and called attention to Müller's early views that, in spite of the physiological division of labor producing the tissues, the properties of all the tissues can be derived from the nuclear substance of a single tissue, as proved by experiments upon the lower animals. Weismann, on the other hand, has held that the course of development is marked by a constant qualitative distribution of his germplasm or hereditary substance, so that, so far as nuclear content is concerned, there are three forms of cells: 1, with nucleoplasm; 2, with nucleoplasm and germplasm; 3, with germ plasm only. Kölliker opposes this idea and maintains that the "idioplasma" passes into all cells, in which it divides in course of development; step by step from the embryonic layers to the tissues, the constructive processes are under the direction of the nuclei containing this hereditary substance; it remains in every nucleus for a long period unaltered, in order to finally, here earlier, there later, impress its constructive forces. In certain elements, as in blood-corpuscles, epidermal scales, etc., it disappears, as the last product of division.

R. Hertwig takes a similar view; since embryonic and adult cell division is differential there must be a form of differentiation in the nucleus, but this does not consist in the total elimination of some qualities and survival of others, nor of a reduction in mass. The mass and the properties remain the same in every cell, the differentiation consists in the activity of certain elements in certain tissues. Thus we may say with De Vries, that different "pangene" may leave the nucleus and enter the cell in different tissues, or with Nägeli, that special "micellæ" come into activity at certain points; in other words, the potential of the nucleus is differently exerted. Here, again, we have the idea of patent and latent hereditary elements, such as appear in the entire individual upon a larger scale.

This is one of the most interesting problems for future investigation, but the direction of research will, I imagine, cover a larger area of cell-content than the nucleus, as we are now swinging back to regard the extra-nuclear archoplasm as an important factor in the process.

In the following paragraph Hertwig expresses his view of nuclear control and cytoplasmic differentiation:

"As I saw in the transformation of the nucleus during fertilization proof that it is the bearer of hereditary substance I recognized a great advance in the fact that the nucleus leaves in the same form in every cell, and in its vesicular capsule is somewhat removed from the metamorphoses of the cells. As Nägeli spread his idioplasm as a net-work throughout the whole body, so, according to my theory, every body-cell contained in its nucleus its quota of hereditary substance, while its specific histological peculiarities were to be regarded as its plasma-products."

The next question *is the fate of the maternal and paternal contributions to the ovum.* Here there is a wide difference of opinion. On the one side Van Bene-

[1] Hugo de Vries: Intracellulare Pangenesis. Jena, 1889.

[2] Die Bedeutung der Zellkerne für die Vorgänge der Vererbung, Zeit. f. Wiss. Zool., 1885. And, Das Karyoplasma und die Vererbung, op. cit., 1886.

den is the leader of those who regard each cell of the body as in a sense hermaphrodite; as we have seen, his views of maturation and the significance of the extension of the polar bodies were colored by this theory, for he regarded the germ-cells as hermaphrodite until one sex was eliminated. But now that the researches of Hertwig have given the last blow to Van Beneden's theory, and it follows that there can be no male and female chromosomes, there still remains room for the analogous view that the maternal and paternal chromosomes remain distinct throughout the course of development, not as sexual elements but as substances with the same racial and specific but different individual tendencies. Rabr, an eminent embryologist, shares this view, and it is supported by Boveri upon the observation that in each division the paternal and maternal elements are kept distinct, and in *Ascaris*, for example, two of the chromosomes of each division figure are paternal and two are maternal. In favor of this hypothesis we may place the following facts: 1st, that there are an even number of chromosome rods in all cells; 2d, that the number is constant throughout all the subsequent changes in the tissues; 3d, that the number is fixed for each species or variety; 4th, that the number is the same in each sex.

Against this *replacement* hypothesis we must consider the extreme complexity of the division process, and the long-resting, or thread stage, in which the chromatin lies in a confused coil. Further, Hertwig argues that if the elements are distinct we should find some evidence that the maternal or paternal part is atrophied or replaced, or excluded from the nucleus, for both parts cannot share alike in the control of the cell. These are Hertwig's grounds for supporting the "verschmelsungstheorie," or *fusion* theory, also advocated by Waldeyer, to the effect that by the complete union of the maternal and paternal substance a new product is formed; in this fusion the law of prepotency may come into play, causing one or the other parental tendencies to predominate, or there may be an even redistribution, whereby, as expressed by Hensen, "the hereditary substance of the son is not that of the father plus that of the mother, but is his own, with a new hereditary form resulting from the combination."

While suspending judgment between these two views as to the separation or fusion of the chromatin, we may appeal to the external phenomena of heredity for light upon the probabilities in the question. First, I refer to the very decided opinion of Francis Galton in regard to particulate inheritance; he is so impressed with the fact that we are made up bit by bit of separate structures derived from different ancestors that he has even suggested that the skin of the mulatto may not represent a fusion of white and black but an excessively fine mosaic in which the colors are so distributed as to give the appearance of blending. We do sometimes observe patches of color as evidence of uneven distribution. As Galton distinguishes two types of structures with reference to inheritance, viz., those which blend and those which do not blend, we might correlate these types with prepotency, replacement, and fusion. Where characteristics do not blend, as in eye-color, it is evident that, while the offspring must receive from both parents the material basis for the formation of the complete color of the eye, either the maternal or paternal material must be prepotent and exclude the development of the other; the logical inference is that the former actively replaces the latter; but it is not necessary that exclusion from the cell chromatin should follow. Now, while some blends seem to support the theory of fusion, the sum total of facts of heredity are strongly against this as a universal principle, for many maternal and paternal structures are preserved in their absolute integrity for generations without the least indication of mixture.

Cell Forces and Heredity.—We have thus far been considering only the chromatin as the heredity substance *par excellence*, and have disregarded for the time the archoplasm or dynamic material of the cell. If we advance upon the hypothesis that a typical cell contains the more or less passive chromatin, and the archoplasm playing upon this chromatin in course of every phase of redistribution, it seems *à priori* improbable that elements which are associated with every vital change should be dissociated in the phenomena of heredity. We might suppose that the mechanics of karyokinesis are exactly similar in every cell of one individual, but it is highly improbable that they should be exactly similar in two individuals. We should, therefore, anticipate the transmission of the chromatin and the archoplasm, implying by this term the dynamic centres especially connected with hereditary function as distinguished from the general functions of metabolism.

This leads us to look for a moment into the life of the cell in its totality. We owe to Dr. Max Verworn [1] a fresh treatment of this subject, based upon experimental researches among the Infusoria, mainly by the extirpation method. As his experiments included only the phenomena of living cells in which the chromatin substance was of course undifferentiated to the eye, he treats of the nucleus as a whole without distinction as to chromatin and achromatin. He concludes that the physiological importance of the nucleus is exhibited in its constant interchange of materials with the remainder of the cell body, only through this interchange does it influence the cell and control its life processes. The interchange is in triple currents, *a*, from outside of cell to cytoplasm; *b*, from cytoplasm to nucleus; *c*, from nucleus to cytoplasm. These movements of interchange are the expression of life phenomena. He compares the *rôle* of the nucleus to that of a cell organoid, like chlorophyll, as not constantly present but as invariably necessary to activity. Thus he believes even the most lowly organized cells have nuclear centres, and that even bacteria are differentiated into nuclear and extra-nuclear areas. Coupled with this idea of nuclear control is the somewhat paradoxical statement that the nucleus is not a dynamic centre, either automatic or regulating, and the conclusion that the nucleus alone cannot be the seat of fertilization and heredity, but both the nucleus and extra-nuclear protoplasm must constitute the material basis of heredity. This conclusion is in the direction of the general reaction of opinion which is now taking place against the centralization of cell-government in the nucleus.

Vague as they must necessarily be, our ideas of cell forces are somewhat further defined by the brilliant experiments of the Hertwig brothers upon germ cell physiology and pathology, which are full of suggestion as to the causation of abnormalities in inheritance. These were begun in 1884 and were first directed to the influence of gravitation upon the planes of embryonic cell division, following up the experiments of Pflüger and Rauber. In 1885 the conditions of bastard fertilization were studied; in 1887 the causes of polyspermy or multiple fertilization; and in 1890 the effects of extreme heat and cold upon germ-cell functions.[2] In general the conclusions reached were that in the normal state there exist regulating forces in the ovum which prevent multiple fertilization or bastard fertilization (*i.e.*, by spermatozoa of other varieties), but these forces are neutralized where the life-energy of the cell is diminished by reagents or by extremes of temperature.

For example, in the normal state the entrance of a single spermatozoon produces a reaction in the ovum-wall preventing the entrance of other spermatozoa, but when the ovum is weakened by chloroform solution two or more spermatozoa enter before the reaction appears; in fact the degree of polyspermy is directly proportional to the intensity of the chemical, thermic, or mechanical disturbance of the ovum. Double fertilization or over-fer-

[2] Experimentelle Untersuchungen über die Bedingungen der Bastardbefruchtung. Jena, 1885. See series of papers in Jenaische Zeitschrift.

tilization has not in a single case resulted in the production of twins, so that Fol's supposition is negatived, although other forms may behave differently. The cell-function may be arrested at any stage by thermic influences; thus two pronuclei, paternal and maternal, about to unite can be held apart by lowering the temperature. Polyspermy also results from a lowered temperature. It is noteworthy that the conditions of bastard fertilization and polyspermy are different; chloroform produces the latter but not the former. Kupffer has, I believe, succeeded in producing twins, or rather two-headed monsters, by multiple fertilization in fishes.

These researches, although made with a different object, re establish the older views as to the interdependence of nuclear and extra nuclear activities, and show that no sharp line of demarcation of function can be drawn between the nucleus as a centre of reproduction and heredity and the cytoplasm, and the cytoplasm as the seat of tissue-building and nutrition. In Boveri's discovery of the archoplasmic centres, or centrosomes, we find positive ground for this broader view. It is connected with the cell phenomena of heredity in the following manner:

While the union of the nuclei in fertilization is the most obvious feature, this union is dependent upon the archoplasm, which rearranges the nuclear elements. If the spermatozoon contains no archoplasm, this power cannot come from the paternal side; but Boveri shows that this is probably not the case and that the spermatozoon brings its centrosome with it, thus entering the ovum with both the paternal chromatin substance and the dynamic material. It is certain from this and from the observations of Roux that the sperm cell is now to be regarded as more than a mere nucleus, that it contains both nuclein and para-nuclein.

Intercellular Forces.—The forces within the different portions of the cell lead us to consider those which must exist between different cells. This is an obscure question at present; but, as I have observed in the close of the second lecture, it is an extremely important one in connection with the problem of heredity. As Professor Wilson writes, "My own conviction steadily grows that the cell is not a self-regulating mechanism in itself, that no cell is isolated, and that Weismann's fundamental proposition is false."

It is a long step between an *à priori* conviction and the demonstration by experiment of a correlation of forces between the cells. This seems to me a most important field of experiment. We have seen in Maupas's work that the contact of the Infusoria initiates a rapid series of internal changes; we have only to conceive of analogous changes taking place when two cells are not in actual contact, as in the phenomena of previous fertilization referred to in the second lecture. Hertwig and others have shown how gravitation is related to cell activity. Roux has destroyed half an embryo with a hot needle in the first stages of segmentation and followed the other half through the stages of subsequent development. Another clever experimenter has turned fertilized ova upside down during the early stages of development, and shown how the protoplasmic pole and yolk-pole forcibly change places. Driesch has traced the connection and meaning of the first plane of cleavage in the embyros of echinoderms. Wilson, in the larva of Nereis, has shown how a certain stage of division in one group of cells affects all the other groups. All these experiments are in the line of determining the relation which exists between internal cell forces and other natural forces. What we must now seek to determine is the relation of cell to cell throughout the body, in connection with the phenomena of heredity.

(To be concluded.)

Fasting for Sixty Days.—A man, ninety-four years of age, recently died in an Indiana town of voluntary starvation. For over eight weeks he is reported to have tasted no food nor stimulant.

POISONING BY CREOSOTE.[1]

By W. FREUDENTHAL, M.D.,

NEW YORK.

The use of creosote internally has become so common since Sommerbrodt's[2] publication of a series of five thousand cases of tuberculosis, in which this drug was administered, that it seems rather remarkable that no case of poisoning by it has thus far been reported.

Before speaking of a particular case of creosote poisoning, which occurred under my observation, I pronounce the day passed when two or three drops of creosote were considered as possessing any therapeutic value. The ancient custom of administering such small doses is only adhered to by very few at present. Nearly all physicians agree that creosote, in order to be effective in the treatment of disease, should be given in much larger doses than in former times.

Bouchard[3] was the first who gave creosote on a larger scale. His formula was used by Sommerbrodt and then abandoned, being substituted by capsules containing creosote 0.5 and balsam of tolu 0.02 gramme. The "toxic" effect of larger doses was, even at that time, so feared, that Sommerbrodt, in his first publication on this subject, stated emphatically that he gave as large a dose as 0.5 gramme daily.

Numerous articles by various writers followed this publication of Sommerbrodt, and most of the authors agree as to the potency and the beneficial effect of this drug. Among these may be mentioned Fräntzel,[4] who, however, is opposed to large doses; furthermore, Peter Kaatzer,[5] von Brunn,[6] Sedziak, of Warsaw,[7] Kossow-Geronay,[8] S. Engel,[9] E. Holm,[10] Schetelig,[11] and, especially, Driver,[12] of Reiboldsgrün. J. Rosenthal recommends the administration of creosote to tuberculous patients in carbonic acid water. Strümpell[13] is one of the few who has not had good results from it. Hopman,[14] however, had given creosote in a few thousand cases of laryngeal and pulmonary tuberculosis with very good effects. He favors large doses, and gives it in the well known formula with compound tincture of gentian. This formula was adopted by me, as well as by others, and I used it continuously up to the end of last year. I gave it in wine, whiskey, brandy, milk, or water, and at times in cod-liver oil. Generally I began with two drops of this solution (1 creosote, 2 tincture of gentian), t.i d., and increased it each day, or every second day, one drop. It is my habit to increase the dose as long as the patient's stomach will accept it without evincing any disturbance. As I have the strong conviction that the more the patient can take the better it is for him, I prescribed 30, 50, 80, and 100 drops of this solution, t.i d., and the majority of the patients stood it most excellently.

What enormous doses some patients can take, by gradual increase, while a sudden overdose will cause intoxication, will be seen by the case which I am about to relate.

Mrs. H. H——, aged thirty, a native of Hungary, consulted me, upon the advice of her family physician, on February 24, 1891, on account of throat trouble. She had been married ten years, and had had nine children, four of which were living. Her father died in his seventieth year, of "heart failure;" her mother is still alive. A year before she consulted me she had caught a cold,

and in the following July a cough developed, with pains in the chest. Three to four weeks previous to this first consultation she felt an irritation in the throat, which increased to actual pain two weeks later, especially while swallowing. Whenever she retired, it "cooked in her throat like boiling oil."

After the acute pharyngitis and laryngitis, from which she was suffering, had disappeared under a mild treatment, I found the following conditions: The mucous membranes of the pharynx and larynx were extremely anæmic, there were superficial ulcerations on the uvula, and deeper ones on the epiglottis and the vocal cords. The posterior wall of the larynx was infiltrated. Physical examination of the chest revealed dulness on both sides down to the second rib, bronchial breathing, and numerous coarse and fine râles all over both lungs. She had had some hemorrhages, the pulse was rapid and extremely weak, she coughed almost constantly, had no appetite, slept poorly, and her strength was so impaired that I agreed with the family physician, who had made a very dismal prognosis. In fact she impressed me almost as moribund.

This was at the time when the tuberculin question had reached its zenith, so I proposed the injection of Koch's lymph, but the hospitals were all so overcrowded that she could not find admittance to any. As I, however, had to administer some treatment, I gave, *faute de mieux*, in the following way:

℞. Creosote..... 10.0
Tinct. gent. co..... 20.0
M. S.: T.i.d., two drops in water; each day one drop more.

I told Mrs. H—— that the larger the dose she could take, the sooner she would feel relieved. Upon inquiring whether she might expect any relief at all from the drops, I told her that it was my belief that if anything could help her this would, for such was my conviction, and in consequence the patient continued increasing the number of drops without asking further advice concerning the creosote prescription.

The following extracts are taken from my book of record:

April 15, 1891.—Mrs. H——, already takes sixty drops of the above solution t.i.d., *i.e.*, sixty drops of pure creosote per day without any difficulty. She feels somewhat better, it "cooks still in the throat," but not as bad as before. She sleeps better, her cough disturbing her but two or three times during the night. Here I will remark that among other instructions I bade her take as much out-of-door exercise as possible, but with the usual precautions.

April 22d.—It still "cooks in her throat" at night time, but she feels considerably better, and takes seventy drops t.i.d. The ulcerations on the uvula are healed, also those on the epiglottis, but new ones have appeared on the latter.

July 5th.—The patient had now reached one hundred drops t.i.d. But her child fell sick, and confined her to the house. Even as small a quantity as ten drops at this time made her dizzy, as though she had taken strong wine, and so she was compelled to give them up entirely as long as she was forced to stay in-doors.

August 12th.—The patient was at Long Branch, where she was continuously in the fresh air, and took again the hundred drops t.i.d. without the slightest effect. The pains in the throat have almost entirely disappeared.

December 6th.—On the right side of the chest no more dulness. Right behind, at the height of the spina scapulæ, râles; left front and behind, few râles. The patient has reached two hundred drops, only taking them twice daily, as she is prevented from going out more often. She improved remarkably during the summer, and looks and feels better than heretofore. Increasing steadily from this period, she reached three hundred drops twice daily by January, 1892.

On January 26th, in my office, I measured three hundred drops, gave them to her, and she left at once to take her customary walk.

On January 29th, 11 A.M., she took the usual three hundred drops, and went walking, but not feeling well returned shortly and drank a glass of wine. Still feeling weak she thought of the drops, which at all times had helped her greatly, and thereupon took another dose of three hundred drops for quicker relief. The results were of the most exciting nature. She had hardly strength enough to drag herself to her bed, where she lay unconscious for eight to nine hours. When I saw her, late in the evening, she looked like one in narcosis. Her eyes were closed and she was puffing and blowing incessantly, her breathing being stertorous. There were loud, coarse râles, which could be heard from a distance, over the whole chest. She was in a state of intense trismus (lockjaw). The teeth were so tightly clenched that it was impossible to separate the jaws. Her lips were cyanotic, and the pupils were contracted and did not react. There was a general loss of sensibilty and paralysis of all reflex movements. Her pulse was 128, and the respiration about 30. She urinated in bed, but the bedclothes were not blackened. The urine was of a light color. After watching the patient a while, I saw signs of gradual recovery. Holding ammonia under her nose she slightly moved her head. A mustard foot-bath was given, and ice applications were made to the head, then she awoke and felt no disagreeable results. Nor did she feel any evil consequence of this intoxication during future treatment. Through a misunderstanding I received no urine of that night and the following day, and it was not until two days later that the urine was sent me, of which I shall speak later.

On reviewing this history we find two important facts of greatest interest: First, the enormous quantity of creosote this patient was able to take; and secondly, the intoxicating effect, after suddenly taking the double quantity of the drug. I have been told that creosote was in former days more expensive than at present; this may have been the reason for its frequent adulteration. Impure carbolic acid was most often substituted for creosote, and therefore the symptoms of creosote-poisoning were almost identical with those of carbolic-acid poisoning. As creosote became cheaper adulteration was no longer profitable, and, to the welfare of our patients, we are enabled to prescribe larger doses, taking it for granted that we can always obtain the pure beech-wood creosote.

The action of creosote is often similar to that of alcohol. It is a substance which mankind can slowly become habituated to, just as arsenic, morphine, alcohol, etc., and the accumulation thereof in the body has—as in all my experience—not been followed by any bad results. When first I prescribed large doses I feared it might affect the kidneys, but repeated examinations in the case of Mrs. H—— reassured me that these parts were perfectly normal. Many other cases showed the same negative results.

Since the year 1887, after treating a few hundred cases of pulmonary consumption in private and dispensary practice, all of whom were suffering at the same time from laryngeal phthisis, I positively affirm that creosote, administered to those who can bear it, becomes more effective the larger the quantity taken.

Having stated the number of drops taken by Mrs. H——, the vital question follows, What was their actual weight? To answer this exactly, I asked the patient for the dropper she had been using, and then Mr. Thomas Latham was kind enough to measure the creosote, which had been bought at his drug store. The following was the startling result: 15 minims equals 45 drops of patient's pipette; 1 minim equals one-third minim creosote; specific gravity of creosote about equals 1.08, average equals one-tenth heavier than water; 300 minims equals 20 c.c. By weight of creosote, about 18.00 grammes; 300 drops from patient's pipette equals 7.34 grammes; creosote equals one-third of mixture, equals

2.40 grammes! Which shows that the patient had taken, in the last two months, 2.4 grammes of pure creosote at a dose; but it is more probable that the dose was 5 grammes daily. The amount impressed me as being very small, although by contrast to former usage it appears large. By Mr. Latham's assistance I soon obtained another pipette, which was so large that, by measuring the same number of drops, we found exactly double the quantity of creosote. Had she used this last pipette she would have taken nine or ten grammes creosote a day.

Although a common fact that there is no standard size of pipettes in our Pharmacopœia, it is so often forgotten that I hold it necessary to draw attention to the above illustration, which taught me to cease prescribing creosote in drops. If we desire uniformity in our experiments and in our results, and if we wish to feel certain of the exact quantity of creosote the patient is taking, we must not prescribe in the form of drops. After a fair trial of different forms of prescription, as in pills, capsules, oil, etc., I finally came to the conclusion that the following is the best method: Give the creosote in pill mass, with liquorice, inclosed in capsules. This double casing prevents evaporation, which often happens when packed alone as pill or capsule. The advantage of no smell nor taste, but principally of the exact measurement, which cannot be obtained with the unreliable pipette, is of paramount value. The above formula is quoted from an old prescription, the author being unknown to me.

When this form is used, we can gradually increase the quantity without any fear of intoxication, until the patient's stomach revolts. How groundless, however, the fear of creosote-poisoning is, is shown by the fact that I could find no clinical report, but the two cases of Taylor and Manouvriez, and in both of these creosote was not prescribed as a medicine by a physician. Taylor[1] reports the following case: "The oil of tartar is a powerful vegetable irritant. In 1832 about ten drachms of it caused the death of a gentleman to whom it had been sent by mistake for a black draught. The druggist who sent it was tried for manslaughter, but acquitted. Its irritant properties are owing to creosote, carbolic acid, and other compounds." I believe that in Taylor's report either he made a mistake, or there is an error in the print, as the oil of tartar is a strong solution of carbonate of potassium and sal tartar, being entirely colorless and not black. But it might have been the oil of tar, which has these qualities. At all events, this case is not clear.

Neither does the case of Anatole Manouvriez[2] throw much light upon this subject. The case treats of a bottle-fed baby, eleven days old, who was given creosote by the mouth. Some minutes later it was found almost suffocated, with a strong odor of creosote, pale, and the mouth half open. The child writhed and made strong efforts to breathe and to cough. From time to time it gave forth hoarse cries, as though suffering from membranous croup. Fluids could not be swallowed, but came back through the nose. The child died after eleven hours, during which time it was able to swallow but once.

Not knowing the amount of creosote given in either of these cases, we can draw no exact conclusions of the effect of the creosote. That the child could not swallow or breathe is very natural, from the deep cauterizing caused by the creosote in the pharynx and larynx (this was shown at the autopsy). Probably this is the same reason why the child kept its mouth open, whereas Mrs. H——'s jaws were tightly closed.

The writhing of the child is a proof of severe pains in the abdomen. Such colicky pains were never present in my patient; except in the last few months, when she took the large doses, she had pains in the lower abdomen, but only during the period of menstruation. Therefore I advised her to omit the drops while unwell. Even at the time when she took the six hundred drops at once she complained of no pains in the abdomen, and I am surprised that Brunton, in his "Pharmacology" (page 69), makes the following remarks: "Large doses (*i.e.*, of creosote) taken internally cause nausea, vomiting, colicky pains, and diarrhœa." These statements appear incorrect in more than one respect. If large doses would cause, as the author says, vomiting, then the greater part, or all of the creosote, would be expelled from the stomach, and it is not easily understood how such a patient could have diarrhœa, or colicky pains, although the latter might be the result of some other cause. Here I should like to mention that in most of the text-books the authors call a great deal of attention to vomiting after large doses of creosote, without any foundation for the statement.[4] My patient never had diarrhœa.

A point of great practical importance is the urine. When I first gave the large doses I was afraid that the patient might develop nephritis, but she never complained about pains in that region, nor did the urine, which was examined by me about every four weeks, contain albumin or casts L. Weber, who administered but small doses, never found a nephritis either. But M. Manges personally informed me that, in treating a man, twenty-five years of age, beginning with the dose of ten drops of Hopenais solution t.i.d., increasing every second day two drops, he found when 150 drops were reached (*i.e.*, 50 drops of creosote) that pains began in the loins, and nephritis had set in (albumin casts, no blood). This nephritis disappeared three days after the medicine was discontinued. The urine, Dr. Manges affirms, was never darkened. This is the only case of nephritis which I know of following the use of creosote.

As I have already stated, through neglect I did not receive the urine until two days after the poisoning. I sent this specimen to my friend Dr. Hugo Schweitzer,[3] who informed me that the urine examined did not contain any creosote, nor its products of transformation.

But of this I am positive, that the urine never was black, nor even darker than usual. Also in this respect there is no similarity to carbolic acid. Even to present date the urine has never been darkened. But as to whether the urine smelled of creosote the day after the intoxication, Mrs. H——and her husband disagree. Several weeks later, on February 13th, the patient, still believing in heroic doses, after taking three teaspoonfuls of the mixture noticed the same strong odor in the urine.

And now, gentlemen, I will conclude with a few remarks on the treatment of creosote-poisoning. When first I saw my patient under the effect of the poisoning by creosote, I thought external excitants the most effective, which they proved to be, as they brought her to consciousness in a short time. Whether this was accidental or not, I dare not affirm. In the future, should you meet with a case wherein these simple remedies do not have the desired results, I would draw your attention to the following note: "The question as to whether the antidotes, consisting of the soluble sulphates, which are so efficacious in carbolic-acid poisoning, would be equally effective in poisoning by creosote derived from beechwood, has been studied by Hare,[5] of Philadelphia. It will be remembered that these substances unite with carbolic acid, forming sulphocarbolates, which are virtually innocuous. In these experiments it was found that animals receiving very large poisonous doses of creosote could invariably be saved if soluble sulphates in sufficient quantity were administered."[6]

To Mrs. H——'s history I will add that after the intoxication she again took the creosote, but was obliged to begin, as she was at all times after a pause, with small doses, increasing them so rapidly that she very soon reached 300 drops. At last the dose was increased to the extraordinary large amount of 500 drops twice daily;

then pneumonia on the left side developed, but she is now convalescing.

Creosote is undoubtedly a strong poison, and must naturally have poisonous effects, either taken without graduation in a large quantity, or as my patient did, increased (although accustomed to a large dose) suddenly to a far larger one. On the other hand, there are but few remedies that one can become so easily habituated to, and which the organism can for so long a time bear as well as creosote

When Beverley Robinson, supported by others, states that the patients in the United States cannot take creosote in large doses, I disagree with him, and firmly believe that there are many in this country who can bear very large doses, and for these the more we administer the happier results we obtain.

FACTS BEARING UPON THE NATURE OF A PSYCHIC MEDIUM.

By R. OSGOOD MASON, A.M., M.D.,

NEW YORK.

Preliminary Observations.—The condition now variously known as animal magnetism, mesmerism, and hypnotism, has been recognized throughout the historic period of the race. Up to the time of Anton Mesmer the condition was looked upon as supernatural, and was associated with oracles, inspiration, prophecy, and miraculous healing.

Mesmer first removed the phenomena from the realm of supernaturalism and referred them to natural causes. For this his name should be honored, and the charlatanry to which, by misappreciation and neglect, he was provoked and tempted, should be forgotten. We admire Galileo for his grand discoveries and his brilliant defence of truths which so vastly enlarged the mental horizon of mankind, and we forget, as best we can, his pusillanimous recantation at the dictation of a mistaken Church.

The nucleus of Mesmer's theory may be stated thus: A needle is placed in harmonious relations with the universe by being magnetized; by an analogous process the human body may be placed in harmonious relations to its surroundings and the universe, and the property or instrument by which this is accomplished is called animal magnetism. Health consists in the orderly performance of the functions of the body. Disease is disorder. As the harmony of the needle with nature is secured and maintained by magnetism, so the order and health of the diseased body are restored and maintained by animal magnetism.

In accordance with this theory he proceeded to magnetize or regulate the magnetic currents of patients affected with paralysis, amenorrhœa, epilepsy, infantile convulsions, and other diseases, and he cured them. The physicians and scientists of that day concerned themselves chiefly with Mesmer's theories, which they did not understand and consequently ridiculed—a mode of procedure not altogether unique—and they rejected his facts accordingly. His patients and others concerned themselves chiefly with his facts and cures, without troubling themselves about his theories. They believed his facts were solid, and they were right.

A century has passed. Mesmer's facts, and a great many more in the same direction, are accepted by the medical profession, but instead of his simple theory of an analogy with a well-recognized fact and law in nature, they have invented a score of different theories, having no analogy or agreement either with nature or with each other.

I wish here to record three simple facts observed by me, and which seem to me to have a bearing upon the much-discussed subject of the force, influence, or medium concerned in producing the phenomena of hypnotism. In doing this I shall use the terms animal magnetism, mesmerism, and hypnotism as synonymous, since they are only different names for the same thing, each having its own appropriateness and its own defect. The term animal magnetism assumes a theory which is not universally accepted; mesmerism associates the name of a man with a group of phenomena with which he was first and most intimately connected; while hypnotism, the name at present most acceptable among modern students of the subject, implies sleep, which is not necessary to the condition which it designates, and, as a matter of fact, often forms no part of the phenomena presented.

The following are the facts to which I would call attention at this time:

1. In the application of animal magnetism or hypnotism, for therapeutic purposes, I often make use of passes in the following manner: Using the tips of the extended or slightly bent fingers, I commence at the top of the head and pass the hands slowly downward over the face, chest, body, lower extremities, and feet, not touching the person, but keeping the fingers at a distance of from a few inches to two or three feet away. Now, I have observed that certainly much more than one-half of the persons so treated are able to feel these passes, more or less distinctly, and to describe the sensation produced. Most patients describe it as a breeze or current; sometimes designated as warm, sometimes as cool, and sometimes as the "pins and needles" sensation. Sometimes the latter sensation is felt so powerfully as to cause sharp pain, convulsive action of the muscles, and loud outcry, the patient at the same time begging me to desist. In those cases where shock and pain are experienced, if the distance of the hands from the patient is increased the unpleasant effect is diminished and becomes bearable. I have met, at least, three well-marked cases of this kind. Generally the effect of the passes is agreeable, and very often results in a true hypnotic sleep. Regarding the sensation described simply as a current or breeze, I would say that it is impossible that it should be caused by any actual current made by the movement of the hand, since the more slowly the passes are made the more distinctly are the sensations perceived; they are also perceived equally well through the ordinary clothing with gloves and boots, or through the ordinary bed-covering. Experiments with the patient blindfolded have often succeeded perfectly. I have made these experiments hundreds of times, often upon most decided and strong-minded sceptics. One of the latter sort, while undergoing the experiment, bounded up from the sofa upon which he was lying, and exclaimed with great emphasis, "Zounds, man, you have a battery somewhere about you!" It is needless to say that such was not the case, and after a few passes the effect became simply noticeable and quite agreeable.

2. Some years ago I had under my care a young lady, twenty-two years of age, a teacher in the public schools, who was subject to the most unmanageable attacks hystero-catalepsy, accompanied, or rather followed, by partial paralysis and protracted periods of double consciousness. The case was reported along with several others before the Neurological Section of the New York Academy of Medicine, October 12, 1888. She was cured by hypnotism. She was, however, under my observation for several weeks after her cure was apparently complete. I also occasionally put her in the hypnotic condition. During her illness the manifestation of abnormal sensitiveness was marked and frequently observed, and I now became convinced that the same condition continued, notwithstanding the disappearance of all unusual manifestations of it. Accordingly I instituted some experiments to test this point. I will describe two of them.

(1.) Taking an old-fashioned copper cent, which I happened to have in my possession, I wrapped it neatly in a bit of ordinary tissue-paper; this was folded in another covering of the same material, and so on until it had acquired six entire coverings of tissue-paper, and was a little, flat, soft, innocent-looking package quite convenient for my purpose. This I took with me, held closely in the palm of my right hand, as I entered the room where my pa-

tient was lying on a lounge. I took a chair as I passed in, and placing it beside the lounge, I sat leisurely down and took her right hand in mine in such a manner that the little package was between our hands, and in close contact with her palm as well as my own. I remarked upon the weather and commenced the routine duty of feeling her pulse with my left hand. A minute or two were passed in banter and conversation intended to thoroughly engage her attention, when, all at once, she commenced to wipe her mouth with her handkerchief and spit and sputter with her lips and tongue as if to get rid of some offensive taste. She then looked suspiciously at me and said, "I wonder what you are doing with me now." Then suddenly pulling her hand away from mine she exclaimed, "I know what it is—you have put a nasty piece of copper in my hand!"

(2.) I took two new, clean glass bottles, exactly alike, fitted with new corks, and put a small dot of ink in the centre of one of the corks, for the purpose of identification. I then filled the bottle with the plain cork with plain Croton water from the faucet in my office. Immediately after I drew a goblet of water from the same faucet, and placing it on my desk I brought all my fingers together in a chump, and then held them for a minute or more over the water in the goblet, as near as convenient to it but without the slightest contact. This water it was, "and nothing more," with which I filled the second bottle, having the marked cork. I then wrapped the bottles separately in thick white paper, put them in a satchel and took them with me on my visit to my patient. During my visit I produced the bottles, taking care that my patient did not see them, much less distinguish the corks. I proceeded to pour out a teaspoonful of the plain water and desired her to taste it. She did so, and I then asked her what she supposed it to be. She replied that she could taste nothing but simple water. I then took a teaspoonful of water from the marked bottle and desired her to swallow it; and on asking her the same question she replied this also was water but that it was peculiar. It was not exactly like aerated water, but that conveyed the best idea she was able to give of how it differed from the plain water; it had a sparkle which she felt in her mouth and felt all the way down as it passed into her stomach. No matter how or in what order the two waters were given her, she never failed to distinguish them, and she always described the difference in the same way.

3. An experiment with the little toy planchette, March 8, 1889. For several days past a young lady friend of the family has been stopping at my house. She is an excellent hypnotic subject; anæsthesia and amnesia are perfect. She travels mentally with me to places she has never seen, and carries out post-hypnotic suggestions with great exactness. For several evenings past we have been amusing ourselves with planchette. She has never seen it used, and at first believes I am making fun of her, until finally something is written of which she knows I am perfectly ignorant, and so she accepts the phenomena as, at least, not intentionally fraudulent. Those who object to the supranormal or extraordinary character of the phenomena of planchette-writing and table-tipping, allege that the movements are caused by the muscular action of the operators. The operators may be honest, but they are deceived, and the movements must be, and therefore are, made by unconscious or automatic muscular action. Regarding the apparent intelligence exhibited in these performances I have at present nothing to say, but that the movements are caused by the muscular action of the operators, conscious or unconscious, I am quite sure is not always the case.

On the evening above mentioned, sitting with the friend whom I have also mentioned, and in the presence of several other intelligent persons, the planchette writing was unusually rapid and violent, and in characters well formed and large. The pain, like that from an electric current, which is often experienced by those assisting at such experiments, was felt by my friend so severely as to be almost unbearable, making her cry out and sometimes remove her hands entirely from the board. Noticing the great power exhibited in the writing, I raised my fingers so that the board slid under them, my fingers remaining in contact with the board, but not following its movements in the slightest degree: the writing still went on as usual. I then called the attention of my friend to what I was doing, and desired her to place her hands in the same position. She did so, and in the presence of three other persons who also witnessed the experiment, the board continued its writing, although neither my own fingers nor those of my friend followed the movements made to produce the writing in the slightest degree, but the board simply slid under our hands. The writing thus made was perfectly distinct and legible.

The tendency of the modern school of hypnotism is to decry and discredit everything which points to an unrecognized force as a cause for the phenomena of hypnotism; especially is this the case when for any such force a physical basis is claimed.

Hysteria, hypnogenous zones, cortical inhibition, unconscious cerebration, imagination, suggestion—these are a few of the various physical and mental states which are seriously considered by the apostles and teachers of hypnotism as real causes, either of the hypnotic condition itself or of the marvellous phenomena which it presents. To hold such opinions can hardly be considered otherwise than illogical, and for the following reasons:

1. Good hypnotic subjects are found among perfectly healthy persons as well as among the neurotic and hysterical.

2. The theory of cortical inhibition while showing ingenuity in its construction fails to show any necessary or special connection with hypnotism. To speak of the inhibitory influence of a stronger over a weaker brain without showing any method or means for the transferrence of that influence, is to leave the theory incomplete and unsatisfactory.

3. Hypnogenous zones are simply specially sensitive points in the body upon which certain external influences very readily produce an effect, but by no means uniformly a hypnotic effect.

4. Regarding imagination and suggestion, persons are often hypnotized who have not the slightest idea that any such effect is expected or desired, and even when they are separated from the hypnotizer, and have no suspicion that any hypnotic influence is being exerted upon them.

In fact all the theories to account for the phenomena of hypnotism, which have so far been looked upon with favor by men of science, have, upon analysis, proved to be partial, insufficient, not covering the ground of accepted facts, altogether lacking harmony among themselves, and not falling into line with other facts in nature. The only theory among them which bears a broad and undisputed relation to the subject is the theory of suggestion, but even this, as we have seen, is incomplete, since persons are put into the hypnotic condition without knowing or suspecting that any such influence was being exerted upon them.

They have been put into the condition by the simple will of the operator, when the subject and operator were separated by distances so great that suggestion by any ordinary process or means of communication was impossible. There is also sometimes a community of sensation between the hypnotizer and subject which is practicable, and has been demonstrated to exist when they were separated by a distance of a hundred feet or more, and when that distance was obstructed by walls and closed doors.

In other words, while suggestion is an agent in some of the phenomena of hypnotism, it is by no means a broad principle underlying the whole body of facts as a cause. And even if it were admitted, it must act through such distances and under such circumstances as to require extraordinary and unknown, if not supranormal, means of transferrence and communication.

For such a purpose it is necessary that there should exist a medium possessing a physical basis, of however rare

and subtle a character, through, or by means of which, psychical influences and impressions may be transmitted.

It is in this relation that the whole subject of animal magnetism, vital force, and the *od* force of Reichenbach will of necessity have to be reviewed and restudied. The leek which the unco-scientific have ridiculed for a century past, will, after all, have to be smelt and tasted.

It is as a contribution to a subject whose interest and influence is bound greatly to increase in coming years that I offer these facts bearing upon the subject of a psychic medium.

REMARKS ON THE OPERATION FOR SECONDARY CATARACT.

By G. HERBERT BURNHAM, M.D., F.R.C.S. Edin.,

OCULIST AND AURIST TO THE TORONTO GENERAL HOSPITAL, AND THE EYE AND EAR INFIRMARY; LECTURER ON THE EYE AND EAR, MEDICAL DEPARTMENT OF THE TORONTO UNIVERSITY, CANADA.

In successful cases of cataract extraction it is unfortunately our lot to have still to contend with the impairment of vision caused by capsular remnants.

The favorite modes of doing the operation of discission are, 1, with one or two needles with sharp points; 2, with a needle with cutting edges; and 3, the division of the capsule by Dr. Wecker's scissors.

I consider that the secret of uniform success lies in the avoidance of too violent dragging upon the ciliary region. I think that the success and freedom from after ill-effects depend upon following out this idea, and that that mode which best enables us to gauge and avoid overstrain is the one which ought to be adopted. I feel that the methods of using one or two needles, and by Dr. Wecker's scissors, are decidedly superior to the cutting needle.

The needles I speak of are those made by Weiss & Son, London, which not only easily pierce the cornea but also retain the aqueous.

By briefly describing the method I pursue I may more clearly make evident my meaning:

The eye is placed under the influence of cocaine, having been previously atropized. I now introduce one needle, and if I find the capsule very friable, the turning process is completed by it alone. If, however, there is much resistance, I do not persevere, but at once pass in the second needle, which, unlike the first one, has a shoulder after Sir W. Bowman's pattern, and then manipulate with these. By doing so cautiously the capsule can be torn without undue traction. After the introduction of the second needle, or in cases in which I have at once made use of two needles, if the effort to divide the membrane shows it to be tough and to render unavoidable the dangerous amount of strain upon the ciliary region, I quickly withdraw these needles. These needles, when properly manipulated, allow none or so little aqueous to escape that the operation with Dr. Wecker's scissors can be immediately entered upon. This latter renders very easy the division of the tough capsule without the dangerous tension already spoken of. The use of the needle with cutting edges, however, requires the rapid performance of the operation, and consequently, as there is no time given to ascertain the character of the capsule, the operator is apt suddenly to realize that it yields much less readily than expected, and only after hazardous tension upon the ciliary region.

The operation for the removal of opaque capsule by the hook is open to the same objection, and in this objection lies, I may say, its great drawback.

Therefore I repeat that the best form of operation is that which allows you not only to feel your way, but at the same time to accomplish your object or to retire without having injured the eye, as the use of the needles in the way described do. In addition, with care in these examinations the eye is so little disturbed that the completion by Dr. Wecker's scissors can at once be proceeded with if time be of great moment.

In regard to after-treatment, the use of atropine, cold applications, etc., are indicated. By following out these directions, the reaction after the operation for secondary cataract is slight. Iritis, iridocyclitis, purulent inflammations and such dreaded sequelæ do not occur in a healthy eye, unless the operator have departed from the principle laid down, or the instruments used have been dirty.

214 John Street.

Clinical Department.

AN EASY BIRTH.

By ERNEST B. SANGREE, A.M., M.D.,

DEMONSTRATOR OF HISTOLOGY IN THE MEDICO-CHIRURGICAL AND THE PHILADELPHIA DENTAL COLLEGE.

Some time since I had an experience, which, though of not of any great interest in itself, seems to me not unworthy recording, rather on account of what might have been. While passing along a street I was accosted by some sympathetic neighbors who asked me if I would go up to look at a colored girl lying up-stairs in the act of labor, with no one by to render any aid. Once there of course I was in for it. The birth had taken place about ten minutes before I reached the room, the child and the placenta having come away together, and the mother not having moved since. After doing what was necessary I left, and being interested in the case on account of the extraordinarily easy delivery, the next day when I called, asked her for the particulars. She was an unmarried girl, of eighteen years of age, and had known she was pregnant, but had not expected the child for a month longer. She had been attending to her regular work until the day before her confinement. On that day she experienced some cramp-like pains, which were not particularly severe and which had entirely left her. The next morning she set about her work as usual, and was doing some sweeping when, about 11 A.M., feeling unwell, she lay down on the bed to rest. Some fifteen minutes afterward she felt the waters break, but being densely ignorant did not know until I told her, either what had happened or what it meant, conscious only that she was relieved by the incident. After another fifteen minutes a slight pain shot across her abdomen, but the first real knowledge she had of what was going on, was an instant afterward when she heard the baby cry. As for the actual passage of the child from the uterus into the outer world, the mother was not aware of it. The placenta had evidently followed at the same instant as the child. Such were the facts in the case, but it is not hard to conceive that they might have been quite different. On account of the girl's utter ignorance of what was about to occur, she might easily have attributed her sense of discomfort to a desire to evacuate the contents of either bladder or rectum, or both (we know how common such desires are at this time), and instead of lying in her bed might have been in the outdoor water-closet—the only one connected with these hovels. Once there, the discharge of the waters and the partial relief experienced, would probably have induced her to remain longer, in the hope that all her discomfort would leave. Or, indeed, in the sitting posture, when the waters broke, everything might have come away at one gush. It is not even necessary to assume that the feeling of discomfort in the lower part of her abdomen might have induced her to seek relief by attempting to evacuate the contents of bladder or rectum. It might simply have been a coincidence that she went to stool at the critical moment when everything was ready to come, and the straining to defecate or urinate have brought along child and placenta in the same manner that they actually did come—like a shot—thus giving her no time to leave the spot, even granting that she were aware of what was taking place. According to the conditions supposed, the child might have dropped into the vault below, leaving the girl in utter ignorance of what happened, and of course innocent in act. In case of discovery and legal investigation,

everything would tend to incriminate the girl: She was unmarried; it was the first time she had been pregnant; she had told no one of the singular accident nor informed anyone of her previous condition; so that between the known evidence and the presumed motive, there is hardly a doubt that in such a case almost any jury would return a verdict of voluntary infanticide.

RETAINED TESTES.

Dr. O. L. Bartlett, of Rockland, Me., writes: "The following rare and very interesting case of lack of development seems to me worth publishing: Mr. A. J. F——, aged twenty two, has always been robust. But his testicles are located in the inguinal canal; the left invisible, known only by tenderness on pressure; the right very noticeable at the external abdominal ring.

"By palpation, patient standing, it can be distinctly mapped out and pressure between the fingers gives that tender, sickening sensation peculiar to the testicles. The testicle seems to have some connection with a flat, oval tumor, about two inches in diameter, just above, to which is given a decided impulse on lifting the testicle upward; a clear wave-like movement also traverses it as though it were a sac filled with fluid. The hypodermic needle, however, excludes it. Coughing brings the testicle more prominently into view, showing it to be of natural shape but smaller than normal in size, and causes a wrinkling over the flat tumor as if from muscular contraction.

"When the patient lies on his back, the testicle disappears within the ring, while the flat tumor remains. The penis is well-developed; the scrotum is present, but is only a small sac. The ejaculatory ducts are normal, and copulative power is perfect. The patient has no physical weakness, and can do hard labor without detriment. I should like to ask if there are many such cases on record, and the probable nature of the flat tumor?"

EUROPHEN IN THE TREATMENT OF THROAT AND NOSE DISEASES.

By WALTER F. CHAPPELL, M.D.,

NEW YORK.

The therapeutic value of many new remedies has been so overestimated by their numerous advocates that one hesitates to recommend a new drug without being certain of the results which may be expected from its use. While not claiming that europhen excels all other remedies of its class, I have been so impressed with it in certain cases that I am convinced it is a remedy worthy of more extended use. Europhen is an amorphous, light yellow powder with very slight odor, and may be used either in powder form or, as it is soluble in alcohol, ether, and all fixed oils, it can be sprayed over the parts. The powder, however, is preferable. Six months ago I began to use it in a case of rhinitis fœtida, and since that time have treated fifteen persons suffering from this disease. I do not propose to burden you with the histories of these cases but to give a short general sketch of the results.

Three cases which received daily treatment during a period of four months, seem perfectly cured and have not the slightest return of the trouble after a month's cessation of treatment, and the mucous membrane of the nasal cavities has a very healthy appearance. The other cases are still under treatment and in various stages of improvement, exceeding anything I have obtained from other methods. The parts should first be cleansed with a half per cent. solution of creolin, and then by means of the small powder-blower recommended by Dr. Andrew H. Smith thoroughly covered with the europhen. This should be repeated every morning and the patient directed to use an ointment at night, consisting of two drachms of europhen to an ounce of vaseline, applied with a camel's hair brush inside the nostrils. This treatment at once excites a watery discharge, which at first is mixed with a quantity of soft yellow mucus, which gradually becomes thinner and lighter in color and less in quantity, until we have only the watery discharge left, with a puffy red condition of the mucous membrane. Whether this benefit will be permanent it is too early to say, but certainly the prospect is very encouraging. I have used europhen in one case of suppurative catarrh where, after removing a good part of the anterior portion of the middle turbinated bodies, I blew in the powder of europhen and with a small probe endeavored to work it into the sinuses. After beginning this treatment the patient improved rapidly, although she had been under my care for eighteen months previous with little benefit. Europhen is also of great value after all operations in the throat and nose, on account of its hæmostatic and antiseptic properties.

A CASE OF ASTHENOPIA AND HEADACHE DUE TO HYPERTROPHY OF THE MIDDLE TURBINATED BONE.

By A. B. KIBBE, M.D.,

SEATTLE, WASH.

The following case is reported because of the peculiar features presented. It is not my opinion that instances like it are common, but I do believe, and my opinion is derived from experience, that headache and asthenopia as well are not so very rarely due to nasal disease. Especially am I of the opinion that hypertrophy of the membrane covering the middle turbinate and thus comprising the septum is a rather frequent cause.

April 20, 1890, I was consulted by Mr. S——, aged thirty-three, by occupation a gambler. I give his occupation lest it be may supposed from the peculiar features in his case that hysteria might have been a factor in producing his symptoms. He stated that for nearly a year he had been unable to read or use his eyes for other close work without a sense of weariness. During the day they seemed too tired, as he expressed it, and he had a constant desire to keep them closed. In getting the history of his trouble, inquiry elicited the statement that he had been a sufferer from almost constant headache in the temporal region, on both sides, for a period of five years. Examination showed emmetropia, all glasses being rejected. Four days' use of atropia, one-half per cent. solution, showed Hm. .50 O. S. and D. These glasses were prescribed for constant use simply as an experiment. I did not see him again until August, when he called to say that his eyes were no better, though he thought the glasses had been of some slight assistance in reading. He had spent the summer in the mountains with the hope the out-door life might benefit him, but had returned disappointed. I then proceeded to examine him for every possible cause. Testing with prisms revealed insufficiency of the external recti 3°. The nasal passages showed a deviation of the septum to the right and an enormous hypertrophy of the left middle turbinated bone, completely filling up the concavity in the deviated septum. The overlying mucous membrane was intensely red, and a ten per cent. cocaine solution failed to appreciably diminish either the injection or the size of the tumor. Here was a dilemma. The muscular insufficiency was in itself sufficient to account for all his symptoms, but with the condition of the nasal passages added an exact diagnosis was impossible. I therefore decided to prescribe $1\frac{1}{2}°$ prisms, base out, and await results. These he wore with no difficulty, and at the end of two weeks reported no improvement. I thereupon proposed to remove the hypertrophied turbinate, and, that failing, make a graduated tenotomy of the internal recti. To this he assented. Using a straight Jarvis snare, I had no difficulty in surrounding the tumor with the wire loop and cutting through it. The piece removed was about ten millimetres long, eight wide, and eleven thick. Bleeding was rather copious, but soon stopped spontaneously. The following day he returned,

saying that he could read without difficulty, and that his headache had nearly ceased. At the expiration of a week his headaches had entirely ceased, and he is now able to read indefinitely without pain or annoyance of any kind.

An examination made February 26, 1892, shows the insufficiency of the externi to have disappeared. Prisms of 8°, base in, are overcome, and in the vertical diplopia test the images are superimposed. This is the most peculiar feature of the case. Why the turbinated hypertrophy should have produced an innervation of the external recti I cannot explain, and the question arises, is it not possible that some cases rebellious to prisms, tenotomies, and every known method of treating asthenopia may have a source similar to the one I report? Any aid in the treatment of these cases will be welcome to those who encounter them, and it is for their benefit I report this case.

A STRANGE MEDICO-LEGAL CASE.

By F. SEMELEDER, M.D.,
MEXICO, MEX.

One evening in May, 1891, a woman, belonging to the middle class, presented herself at a police station of this city, crying and in great distress, asking for medical assistance, because her husband was very sick and had probably poisoned himself. The employee and surgeon went to the patient's house, found him almost dying; signs of disorder in the house and room, as is natural in case of such an accident. On the table there was a small vial labelled morphia. The sick man was taken to the municipal hospital of San Pablo, where he died the next morning, without having recovered his consciousness even for a minute. The widow and family were extremely anxious to have the corpse delivered to them to take home. They wished to wash and dress it, and have a funeral. However, as there were some strange features about the case, they were denied their petition and a post-mortem ordered, which furnished the following curious data:

No external lesion was found. The nostrils and mouth showed signs of a bloody discharge and the nasal cavity was full of bloody cotton. After opening the skull no signs of congestion of the brain were noticed; after taking out the brain, at the base of the anterior lobes a small portion was reduced to a pulp. On the base of the skull the cribriform plate of the ethmoid bone showed fractures communicating with the nasal cavity and corresponding to the brain lesions before mentioned. These fractures were probably caused by some pointed instrument (afterward it was known to have been an iron hook) introduced with great force and turned round in various directions. A little farther back, and in the right fossa of the cerebellum, between the dura mater and bone, there was an extravasation of coagulated blood; after removing this blood a fracture was discovered at the base of the skull, which parted from the occipital foramen and extended into the mentioned fossa.

The mouth, nasal, and pharyngeal cavities were full of blood-clots; above the soft palate, in the fundus of the pharynx, a small wound made with a pointed instrument and only interesting the mucous membrane. The sixth, seventh, eighth and ninth ribs on both sides were fractured, near the insertion of the cartilages and on the pleura were corresponding ecchymoses. The lungs showed no congestion, as is found in morphia poisoning. In their lower and posterior parts were found remarkable subpleural ecchymoses, like those occurring in cases of sudden death.

It is evident that the lesion, partial destruction of the brain, was the cause of death in this case. The murderer, whoever it was, must be the possessor of certain anatomical knowledge and of a great amount of shrewdness. No further particulars are known, as the case has not yet been brought to a trial.

EPITHELIAL CARCINOMA OF KIDNEY.

Reported by JOSEPH WILLIAM STICKLER, M.D.,
occurring in the practice of
WILLIAM PIERSON, M.D.,
ORANGE, N. J.

Mr. P——, aged forty-five, agriculturist. Never had specific disease. No history of cancer in family. While in the South he had a severe attack of malarial fever, after recovering from which he observed a tumor in the right side of his abdomen. His physician regarded it as an enlarged liver. At that time he was up and about. Had no pain or jaundice. His appetite was good and bowels regular, but he lost in weight. The emaciation became more and more marked as the disease advanced. He came North in June, 1890, and placed himself under the care of Dr. William Pierson, Orange, N. J. At that time there was dulness from the nipple to a point two inches below the umbilicus, and from the spine to the cartilage of the tenth rib on the right side. It was thought that the free border of the liver could be felt. The tumor was hard to the touch and irregularly nodular. No fluctuation could be discovered till November, 1891, when a small area of fluctuation was appreciated in the axillary line, about midway between the upper and lower borders of the tumor. By means of a hypodermic needle some fluid was withdrawn, which consisted of pus and blood-cells, with a few other cells which had the appearance of cancer-cells. The urine gave no evidence of renal disease. The patient was seen at this time by several physicians, among whom were Professors C. A. Lindsley and F. S. Dennis, all of whom regarded the tumor as a malignant growth of the liver.

The patient continued to lose flesh and strength, although he never complained of pain. Death occurred January 23, 1892.

Post-mortem examination was made by Drs. Mitchell and Stickler. Present: Drs. Pierson, Bayles, Harvey, Bradshaw, Maghee, and Gunther.

The lower extremities were very œdematous. The upper extremities, chest, and head were without visible fat. The veins of the chest and abdomen were markedly enlarged. The circumference of the abdomen at the level of the ensiform cartilage was 43 inches; at the level of the umbilicus, 44 inches; three inches below the umbilicus, 47½ inches.

When the abdominal cavity was opened there appeared a large tumor, yellow in color, and lobulated. There was some ulceration of the tumor, upon its surface, in the axillary line, about midway between its upper and lower borders. At one point on the right side of the tumor the peritoneum was intimately adherent, below and posteriorly there were also some attachments, but they were easily broken away.

The intestines were adherent above, below, on the left side, and posteriorly. The omentum was attached anteriorly. The liver was normal in appearance, but was attached to the upper surface of the tumor. The spleen, left kidney, pancreas, stomach, bladder, and intestines were normal in appearance.

The tumor weighed 43 pounds; measured 32¾ inches in circumference at its most contracted point, and 42 inches in its long diameter. The growth was kidney-shaped. Within its interior was a cavity about as large as a fig, caused by an ulcerative process.

Inasmuch as a carcinomatous kidney weighing forty-three pounds is not frequently encountered in practice, it was thought a published record of this case might prove interesting.

What Will the Children Do Now?—The Massachusetts Legislature, on March 8th, by an overwhelming majority, passed to be engrossed the bill making it a criminal offence to manufacture, sell, or expose cigarettes for sale within the limits of the State.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street

New York, April 23, 1892.

A WARNING TO CHICAGO.

THE foreign medical journals are beginning to comment upon the insanitary condition of Chicago in a way which ought to compel attention on the part of the authorities of that city. From a number of articles, editorial and other, which have been written on the subject, we select the following from a recent issue of the *Medical Press* as a moderate expression of the distrust of Chicago that is growing abroad :

"In view of the fact that in the year 1893 the city of Chicago will be visited by vast numbers of people, who will be attracted thereto by the great World's Fair, it is important that the sanitary condition of the place shall be such as to remove the feeling of uneasiness among those who will resort to it for purposes of pleasure. At the present time, however, this cannot be said to be the case, as typhoid fever is shown to have a tenacious grip on the city, where it is estimated that no fewer than twenty thousand cases of the disease occurred in the year 1891, the total number of deaths from this cause in the twelve months named having been 1,997. The whole question has been carefully worked out in a paper, read before the American Statistical Association recently, by Professor W. T. Sedgwick, of the Massachusetts Institution of Technology, and Mr. Allen Hazen, chemist to State Board of Health at Lawrence, and the results given above are those which this communication revealed. The Health Commissioner of Chicago has called the figures into question, and has characterized the statements as ridiculous ; but, as proved by accurate examination of the mortality returns of the city, they are only too well founded, while in January of the present year no fewer than 219 deaths from typhoid fever took place in Chicago. The prevalence of the disease is attributed to the unsatisfactory condition of the water-supply of the place, which is at present derived from the river, and is occasionally polluted with sewage. In view of these facts it is very properly insisted on that immediate steps should be taken to improve the character of the supply, which it seems can easily be done by carrying out certain measures to insure an absolutely uncontaminated supply. That no time ought to be lost in securing so necessary a reformation is apparent, and especially when it is reflected that the floating population of Chicago will be so largely augmented by the rush of visitors from all parts of the world who will hurry to the Exhibition to be held there next year."

This is not a matter of purely local concern. If it were, the rest of the country could attend to its own affairs and let Chicago excuse herself for the sacrifice of the lives of her citizens in the best way she could. But Chicago will be for the time being, in the eyes of the world, the representative of the entire country, and her responsibilities are consequently much greater. If she does nothing to prevent typhoid fever by purifying her water-supply, the shame and disgrace will react upon the whole country, although the direct loss will fall upon the city itself. If it became generally known abroad that Chicago is a pest-hole, the expected millions at the World's Fair will fail to materialize, for people can find other and more pleasant means of suicide nearer home.

The figures are there, showing that typhoid fever is endemic in Chicago, and they cannot be pooh-poohed away by the city authorities. The cause of the endemic is known to be in a polluted water supply. The remedy is simple, even though it may be expensive. Is Chicago willing to bear that expense now, or does she prefer that the Fair should be a flat failure?

As the Illinois State Board of Health has begun to investigate the matter, under the efficient direction of Dr. Rauch, we may indulge a reasonable hope that the city will be forced to act and to act promptly.

HOMES FOR MEDICAL SOCIETIES.

WE recently recorded the fact that sufficient money had been secured in Vienna to insure the erection of a suitable building for the use of the Imperial Royal Medical Society of that town. In Berlin it is announced that a similar but more elaborate building, to be called the Langenbeckhaus, and to be used as a home for the local medical societies, is in process of erection. The German Emperor subscribed $25,000.

London has long had a place for the meetings of its medical societies, and New York, in its Academy of Medicine, is perhaps as yet ahead of all other cities. The great utility of such places cannot be exaggerated. They promote the social spirit, encourage the more frequent interchange of views, and lessen the tendency to the formation of cliques. They keep the profession more actively interested in medical progress, and more uniformly acquainted with all that takes place in the scientific world. It should be one of the earliest duties of physicians in all cities to secure a common home, and we rejoice to see the movement extending.

A GENTLEWOMAN'S EFFRONTERY.

THE feelings of some of our esteemed brethren practising in London are being lacerated in a most heartless manner by a bold and shameless lay journal called the *Gentlewoman*. It appears that this disesteemed contemporary publishes each week a column entitled "Medicos under the Microscope," which gives a little sketch, accompanied by a portrait, of the life, medical training, and special capabilities of some more or less well-known London physician or surgeon, preferably a specialist. The outrage is the more apparent when it is stated editorially by this most offensive *Gentlewoman*, that the subjects of these little biographies have had no hand in their

preparation, nor even knowledge of their production. Yet, in spite of this, there are men (of course only those who have had the good fortune to escape this harrowing publicity) who are actually mean enough to ask for "some assurance from these gentlemen that these descriptions are in fact published without their own co operation." Thus the victims of this contemptible publication have not only to suffer a cruel wound to their modesty and to see themselves and their works exposed to the glare of hateful publicity, but they are even subjected to the innuendoes of the wicked and the unjust chidings of saddened friends. But it is not only those few whose privacy has already been invaded that are tortured by this fiendish *Gentlewoman*, for there yet remain several hundred modest practitioners and consultants in London who live in mortal dread from week to week, each one fearing that his turn may come next, and that his name will be added to the list of these poor sufferers from an unsought advertisement. It is a dreadful thing to wait with anxious expectancy for the lightning to strike—and then not be struck after all.

THE THERAPEUTIC VALUE OF ELECTRICITY.

In September, 1891, an electro-therapeutic congress was held at Frankfort, Germany, and another in Philadelphia, Pa. The proceedings of both these congresses have been published and have received considerable attention. The methods and aims of the two meetings were, however, in singular and instructive contrast. While the Philadelphia congress devoted itself to the publication of new methods, new instruments, successful results, and, in general, to the exploiting of electro-therapeutics, the Frankfort congress took directly the opposite course. The single aim in all the discussions was to find out if electricity did any good whatever; if so, in what classes of cases and by what methods. Throughout the meeting there pervaded a thoroughly critical and scientific spirit, which we trust our American electro-therapeutists will in the future endeavor to emulate.

A perusal of the transactions of the Frankfort congress, and of some German articles published about the same time on the same subject, leads one to the conclusion that electricity comes out fairly well as a therapeutic agent, and that it will hold a good place in the armamentarium of the physician. The "happy therapeutist" who has somewhere imbibed the opinion that "electricity is life," with all the jocund and deep-seated powers which that implies, will feel, perhaps, disappointed over the actual curative effects which have been found to be possessed by the electrical current. But there is enough in it to help him and his patients a great deal, after all.

In paralyses due to injuries or disease of the peripheral nerves, electricity, while not a specific, does good in promoting and hastening cure, or in starting into activity again a stagnant reparative process.

In organic diseases of the spinal cord, electricity seems to have no direct effect upon degenerative or inflammatory processes. Yet there are occasional exceptions, and in most cases some indirect benefit results from the stimulation of muscles and peripheral nerves, or by modifying the central circulation.

In organic diseases of the brain, it has never been thought by serious persons that the electrical current could directly modify inflammation or softening. But the mechanical and psychic effects are often profoundly useful. Wernicke's theory that stimulation of the paralyzed muscles tends to develop new sensory-motor areas, and furnish new centres in place of those injured, is plausible and has some clinical support.

There is a general agreement that electricity has a curative effect on many forms of neuralgia, and a sedative and helpful effect on many kinds of spasmodic troubles. Electricity, however, has been supplanted by the analgesics in the treatment of acute attacks. Great confidence is expressed by the French school in the use of faradism in Basedow's disease; and all agree that in neurasthenic and hysterical conditions electricity is of value. Whether its action is "suggestive," or mechanical, or biological, does not much matter, except as a question of pure science.

The Franklinic electricity has been found to have a specific effect on metabolism, increasing it more than is done by other forms.

The effect of such discussions as were had at the Frankfort congress should be to make the physician more cautious in using electricity, but more confident and intelligent when he does apply it.

It would be a most fortunate thing if some of our numerous medical congresses would take up and study critically others of our apparently well-established remedies. Would cod-liver oil stand the test, or the hypophosphites? And that superiorly wonderful tincture of the chloride of iron, would it really prove better than iron rust? The question might be asked whether invalid humanity would not be better without strychnia, or alcohol, or Fowler's solution.

We trust some day to see the medical profession enter upon a phase of therapeutic regression.

A PLEA FOR VIVISECTION.

A certain Mr. Lilly, an English anti-vivisectionist once wrote that "the results obtained by researches in the latrine and brothel are of precisely the same value as those which the vivisector derives from the torture trough." He adds: "I regard it (that is, vivisection) as absolutely unethical, and should condemn it unhesitatingly, however great the advantage resulting from it might be. . . . I should be glad to see legislative sanction given to the proposal that vivisectors should make experiments on themselves and on one another."

In interesting opposition to such mad sentiments as these, Rev. L. J. Wallace has written an article in the *Westminster Review* in favor of vivisection. Such a position is evidently considered a very extraordinary one to be taken by a layman in England, where anti-vivisection sentiments pervade not only the Philistine, but the Bohemian and artistic worlds.

Mr. Wallace, says the *British Medical Journal*, after discussing the utilitarian aspect, approaches the broad ethical issue in a dispassionate and judicial spirit. Reviewing the evidence on both sides, he recognizes that the anti-vivisection propaganda has been the outcome of emotions, misled by "descriptions" of a very partial and

very exaggerated character; and he warns those who so recklessly impute evil, that it may be immoral for the man of science to abstain from vivisection.

"A great moral force is working on behalf of the physiologists. Suffering and death are on every side of them, and if by any fair means they can alleviate the one and retard the other, they have no right to neglect these means. They are, so far as their power extends, debtors to humanity, and they would act an immoral part if they declined to make any legitimate effort to discharge this debt."

News of the Week.

Dr. John G. Rosman died very suddenly recently at his home in Brooklyn. He had been visiting his patients and was sitting in a chair in his office when the intracranial hemorrhage occurred which terminated his life. He was born in Hudson, N. Y., in the year 1835, and had been in active practice for thirty-four years. He was a prominent member of several clubs, and at one time served the Brooklyn Board of Education. Dr. Rosman was an enthusiastic sportsman and always passed his summers fishing and hunting in the Adirondacks, of the sanitary advantages of which region he was one of the earliest advocates.

The Alumni Association of the College of Physicians and Surgeons of Baltimore.—The annual "alumni lectures" were delivered before this Association by Dr. W. E. B. Davis, of Rome, Ga., on the evenings of April 11th and 12th. The subject was: "Peritonitis: its Etiology and Treatment."

Medical Association of the State of Alabama.—The annual meeting of this Society was held in Montgomery on April 12th, 13th, 14th, and 15th.

Cuban Medical Degrees.—Dr. A. M. Fernandez de Ibarra, of 140 West Tenth Street, writes: "In your issue of April 2, 1892, speaking about the Cuban degree of M.D., you say that the Spanish Minister of Foreign Affairs has proposed to take away the power of the University at Havana to grant the degree of M.D., reducing it to the position of being only allowed to grant a license to practise. Permit me to state that it was not the Minister of Foreign Affairs, but the Minister for the Colonies, who has already ordered the University of Havana to discontinue the granting of the degree of Doctor, not only in Medicine, but in all the other faculties of the University. His object is, he says, to have the Cubans go to Madrid for their higher degree, in order to make them better acquainted with the splendor and greatnesses of the mother country. I think his true purpose is to curtail the noble aspiration of the Cuban youth for learning, liberty, and culture—Machiavelism pure and simple."

Not Six at a Birth.—A telegram to the *Times* not long since conveyed the startling information that a Mrs. C. K. Smith, residing near Holly Springs, Miss., had given birth to six healthy boys, weighing in the aggregate forty-five pounds. Dr. Crampton, of this city, wrote to the postmaster of Holly Springs to inquire as to the correctness of this item, and received answer that there was no such woman there as Mrs. C. K. Smith, and that no such occurrence had taken place. Probably of equal truth is the still taller story cabled here from the United States of Colombia concerning a French woman living there who had given birth to septuplets.

The Brooklyn Dermatological and Genito-Urinary Society was organized on March 11th. The election of officers resulted in the choice of Dr. S. Sherwell for *President*, A. E. Smylie, *Vice-President*, and G. D. Holsten, *Secretary and Treasurer*. Meetings are to be held on the first Friday of each month. We congratulate the new Society upon not having adopted the name andrology, the use of which to designate a class of diseases, chiefly venereal, is a base slander upon the male sex.

Dr. Edward Wight Clarke, of Englewood, N. J., died on April 11th of scarlet fever. He was born in Manchester, N. H., October 20, 1862, and was graduated from the College of Physicians and Surgeons in 1887, taking the third Harsen prize for proficiency in the examination. After serving on the surgical house-staff of the New York Hospital he began practice in Englewood. He devoted his attention chiefly to surgery, and devised the method of treating fractured patella by subcutaneous ligature, called by his name. He married Miss Virginia L. Banks in 1888, and this wife and two children survive him.

The Pan-American Medical Congress.—The Committee on Permanent Organization met at St. Louis, October 14, 15 and 16, 1891, and adopted a series of General Regulations for the permanent organization of the Pan-American Medical Congress, and a series of special regulations for the government of the first meeting, and recommended that the incorporators adopt both series of regulations as the organic law of the Congress. Pursuant to such regulations the following general officers were elected, viz.: *President*, William Pepper, M.D., LL.D., Philadelphia, Pa.; *Treasurer*, Abraham M. Owen, A.M., M.D., Evansville, Ind.; *Secretary-General*, Charles A. L. Reed, M.D., Cincinnati, O. *International Executive Committee: Argentine*—Dr. Pedro Lagleyze; *Bolivia*—Emilio de Tomassi; *Brazil*—Dr. Carlos Costa; *British North America*—Dr. James F. W. Ross; *British West Indies*—Dr. James A. De Wolf; *Chili*—Dr. Moises Amaral; *Colombia*—P. M. Ibañez; *Costa Rica*—Dr. D. Nuñez; *Ecuador*—Dr. Ricardo Cucalon; *Guatemala*—Dr. José Monteris; *Haiti*—Dr. D. Lamothe; *Spanish Honduras*—Dr. George Bernhardt; *Mexico*—Dr. Thomas Noriéga; *Nicaragua*—Dr. Juan I. Urtecho; *Peru*—Dr. José Cassamira Ulloa; *Salvador*—Dr. David J. Guzman; *Spanish West Indies*—Dr. Juan Santos Fernandez; *United States*—Dr. A. Vander Veer; *Uruguay*—Dr. Jacinto De Leon; *Venezuela*—Dr. Elias Roderiguez. The members for Hawaii, Paraguay, Santo Domingo, and the Danish, Dutch, and French West Indies, have not yet been appointed.

The Auxiliary Committee nominated by the various members of the Committee on Permanent Organization each for his own state, and already commissioned by the Chairman, was confirmed. The election of officers of sections was begun, but time would not permit of the completion of the list, which was referred to a special committee with power to act. It has been deemed inexpedient to

publish the list until it is completed, which can hardly be accomplished before the meeting of the Committee on Permanent Organization at Detroit in June; but the organization of particular sections will be announced through the medical press as rapidly as officers are elected by the Special Committee.

In accordance with the wish of the Committee on Permanent Organization, as expressed in Special Regulation No. 4, Drs. I. N. Love, A. B. Richardson, L. S. McMurtry, R. B. Hall, T. V. Fitzpatrick, and Charles A. L. Reed, met in Cincinnati and signed the legal form of application for Articles of Incorporation of the Pan-American Medical Congress, which Articles of Incorporation were duly issued by the Secretary of the State of Ohio, under date of March 15, A.D. 1892. At a meeting of the Incorporators held March 16, 1892, the following regulations, general and special, recommended by the Committee on Permanent Organization, were formally adopted as the organic law of the Pan-American Medical Congress, in accordance with the laws of Ohio, and all elections had by the Committee on Permanent Organization, in accordance with such regulations, were confirmed and made a part of the laws of the Congress:

GENERAL REGULATIONS.—*Title.*—1. This organization shall be known as the Pan-American Medical Congress, and shall meet once in —— years.

Membership.—2. Members of the Congress shall consist of such members of the medical profession of the Western Hemisphere, including the West Indies and Hawaii, as shall comply with the special regulations regarding registration, or who shall render service to the Congress in the capacity of Foreign Officers.

Officers.—3. The Executive Officers of the Congress shall be residents of the country in which the Congress shall be held, and shall consist of one President, such Vice-Presidents as may be determined by special regulations, one Treasurer, one Secretary-General, and one Presiding Officer and necessary Secretaries for each section, all of whom shall be elected by the Committee on Organization, and there shall be such Foreign Vice-Presidents, Secretaries, and Auxiliary Committees as are hereinafter designated.

The Committee on Organization.—4. The Committee on Organization shall be appointed by the representative medical association of the country in which the Congress shall meet. This committee shall select all domestic officers of the Congress, and shall at its discretion confirm all nominations by members of the International Executive Committee, and in the event that any member of the International Executive Committee shall fail to nominate by the time specified by special regulation, the Committee on Organization shall elect officers for the country thus delinquent. It may appoint vice-presidents and auxiliary committeemen in foreign countries independently of nominations by the members of the International Executive Committee. It shall appoint Auxiliary Committees, arrange for the meeting, and frame special regulations for the session of Congress for which it was appointed. It shall make a report of its transactions to the opening session of the Congress.

The International Executive Committee.—5. There shall be an International Executive Committee, which shall be appointed by the first Committee on Organization, and which shall consist of one member for each constituent country. This committee shall hold permanent tenure of office except that when a member shall fail to be present at a meeting of the Congress, his office shall be declared vacant and the vacancy be filled by election held by the registered members from the country from which he was accredited. In the event of no representation whatever from the country in question, the members of the International Executive Committee present shall determine what disposition shall be made of the office. It shall be the duty of each member of the International Executive Committee to nominate from the medical profession of his country one Vice-President for the Congress, and one Secretary for each section of the Congress, and to forward the same to the Chairman of the Committee on Organization; except that in any country in which the Congress shall meet it shall be the duty of the member of the International Executive Committee for that country to request his representative national medical association to appoint a Committee on Organization, which Committee on Organization shall discharge the duties designated in Regulation 4. Members of the International Executive Committee shall also nominate such Auxiliary Committees, and shall furnish such information as the Committee on Organization may request.

6. The Committee on Organization may at its discretion cause the Congress to be incorporated, which incorporation shall hold only until the final disbursement of funds for the session held in that particular country. In the event of such incorporation such officers shall be elected and in such manner as may be required by law.

7. The following shall be considered as the constituent countries of the Pan-American Medical Congress: Argentine Republic, Bolivia, Brazil, British North America, British West Indies (including B. Honduras), Chili, Honduras (Sp.), Mexico, Nicaragua, Paraguay, Peru, San Salvador, Colombia, Costa Rica, Ecuador, Guatemala, Haiti, Hawaiian Islands, Santo Domingo, Spanish West Indies, United States, Uruguay, Venezuela, Danish, Dutch, and French West Indies.

8. The Sections of the Congress shall be as follows: (1) General Medicine, (2) General Surgery, (3) Military Medicine and Surgery, (4) Obstetrics, (5) Gynecology and Abdominal Surgery, (6) Therapeutics, (7) Anatomy, (8) Physiology, (9) Diseases of Children, (10) Pathology, (11) Ophthalmology, (12) Laryngology and Rhinology, (13) Otology, (14) Dermatology and Syphilography, (15) General Hygiene and Demography, (16) Marine Hygiene and Quarantine, (17) Orthopædics, (18) Diseases of the Mind and Nervous System, (19) Oral and Dental Surgery, (20) Medical Pedagogics, (21) Medical Jurisprudence.

Languages.—9. The languages of the Congress shall be Spanish, French, Portuguese, and English.

Auxiliary Committees.—10. The Auxiliary Committee shall consist of one member for each medical society or one for each considerable centre of population in each of the constituent countries of the Congress. Nominations for the Foreign Auxiliary Committee shall be made to the Chairman of the Committee on Organization by the members of the International Executive Committee, each for his own country, except that in the country in which the Congress is to be held nominations shall be made by

the Committee on Organization. Appointments on the Auxiliary Committee shall hold only for the meeting for which they were made. Members of the Auxiliary Committee shall be the official representatives of the Congress in their respective localities. It shall also be their duty: (1) To transmit to the profession of their respective districts all information relative to the Congress forwarded to them for that purpose by the General Officers. (2) To co operate with the Officers of Sections in securing desirable contributions to the proceedings of the Congress. (3) To furnish to the General Officers such information as they may request for the purpose of promoting the interests of the Congress. (4) To cause such publicity to be given to the development of the organization as will elicit the interest of the profession and secure attendance upon the meeting, and they shall discharge such other duties as will promote the welfare of the Congress.

Special Regulations of the First Congress.—*Time and Place of Meeting.*—1. The First Pan-American Medical Congress shall be held in the City of Washington, D. C., September 5, 6, 7, and 8, A. D. 1893.

Registration.—2. The Registration fee shall be $10.00 for members residing in the United States, but no fee shall be charged to foreign members. Each registered member shall receive a card of membership and be furnished a set of the "Transactions."

Abstracts, Papers, and Discussions.—3. Contributors are required to forward abstracts of their papers, not to exceed six hundred words each, to be in the hands of the Secretary-General not later than July 10, 1893. These abstracts shall be translated into English, French, Spanish, and Portuguese, and shall be published in advance of the meeting for the convenience of the Congress, and no paper shall be placed upon the programme which has not been thus presented by abstract. Papers and discussions will be printed in the language in which they may be presented. All papers read in the Sections shall be surrendered to the Secretaries of the Sections; all addresses read in the General Session shall be surrendered to the Secretary-General as soon as read; and all discussions shall be at once reduced to writing by the participants.

Incorporation.—4. The Chairman of the Committee on Organization shall cause the Congress to be incorporated under the laws of Ohio, and fifteen trustees shall be elected in accordance therewith, who by by-laws and through the Executive Committee shall supervise all receipts and disbursements by the Treasurer in accordance with the laws of Ohio. The President, Secretary-General, Treasurer, the Member of the International Executive Committee for the United States, and Chairman of Sections shall be *ex officio* members of the Board of Trustees.

Foreign Nominations.—5. All nominations by the International Executive Committee must be in the hands of the Chairman of the Committee on Organization by June 1, 1892, and in default thereof the Committee on Organization shall elect officers for countries thus delinquent.

The Organization of Sections.—6. The officers of each section shall consist of —— Honorary Chairmen, who shall be residents of the constituent countries of the Congress; one Executive Chairman, who shall organize the work of the Section, direct its deliberations, and deliver an inaugural address at its opening session; one English-speaking Secretary and one Spanish speaking Secretary, residents of the United States, who shall co-operate with the Executive Chairman in conducting the correspondence of the Section; and there shall be one Secretary for each Section, resident in each additional constituent country of the Congress.

Domestic Auxiliary Committee.—7. The Auxiliary Committee for the United States shall be elected by the Committee on Organization, and shall consist of one member for each local medical society, or, in the absence of medical organization, then one in each considerable centre of population, which Auxiliary Committee shall co-operate with the Committee on Organization and with the General Officers in promoting the welfare of the Congress. Nominations for the Auxiliary Committee shall be made by members of the Committee on Organization, each for his own State, except that in the failure of any member to make such nomination by January 1, 1892, or in the inadequacy of the same, the Chairman of the Committee on Organization shall supply the deficiency.

Executive Committee.—8. The Board of Trustees shall designate seven members, including the President, Treasurer, Secretary-General, and Member of the International Executive Committee for the United States, who shall comprise an Executive Committee which shall transact all business of the Congress *ad interim* in accordance with by-laws adopted by the Board of Trustees.

Amendments.—9. Amendments to these Regulations can be made only by the International Executive Committee on a majority vote, ten members constituting a quorum, at any meeting of the Congress.

Pursuant to the Laws of Ohio and the Regulations adopted as above, and in accordance with nominations by the Committee on Permanent Organization, the Incorporators elected fifteen Trustees as follows: Dr. W. T. Briggs, Tennessee; Dr. George F. Shrady, New York; Dr. P. O. Hooper, Arkansas; Dr. S. S. Adams, D. C.; Dr. H. O. Marcy, Massachusetts; Dr. J. F. Kennedy, Iowa; Dr. H. D. Holton, Vermont; Dr. L. S. McMurtry, Kentucky; Dr. N. S. Davis, Illinois; Dr. Levi Cooper Lane, California; Dr. I. N. Love, Missouri; Dr. Hunter McGuire, Virginia; Dr. J. C. Culbertson, Illinois; Dr. A. Walter Suiter, New York; Dr. C. H. Mastin, Alabama. Drs. L. S. McMurtry (Ky.), I. N. Love (Mo.), and W. W. Potter (N. Y.) were designated to act as members of the Executive Committee. The organization of the Congress is complete in British North America, the British West Indies, the Spanish West Indies, Guatemala, Nicaragua, United States of Colombia, Brazil, Uruguay, Venezuela, and the Argentine Republic. It is confidently expected that the nominations from the remaining countries will be in by June. It is expected to announce the completed organization of the Congress, its Sections, and Auxiliary Committees, domestic and foreign, by July 1, 1892. On behalf of the Committee on Permanent Organization, Charles A. L. Reed, *Chairman;* J. W. Carhart, *Secretary.*

Dr. R. H. Fitz has been appointed Professor of the Theory and Practice of Medicine in the University of Harvard.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 3, 1892.

ALFRED L. LOOMIS, M.D., PRESIDENT IN THE CHAIR.

Cases of Appendicitis Illustrating Different Forms of the Disease, with Remarks.—DR. CHARLES MCBURNEY read the paper (see p. 421).

Relation of Physician and Surgeon.—DR. FRANCIS DELAFIELD was called upon to open the discussion. He thought the point of view of the physician and that of the surgeon regarding appendicitis must differ considerably. The physician was called in to make a diagnosis and to give advice as to what should be done, while the surgeon was called in to do it. The responsibility in the two positions was not the same. He would limit his remarks to the class of cases discussed in the paper. The first three were, he thought, of a kind which did well under an operation—they all recovered. They might also have recovered without an operation, but that we did not know. Then the surgeon had the advantage in that when his patients recovered they were not liable afterward to have abscess, or septic poisoning, or recurrent attacks. But there was one drawback to a cure by surgery, namely, leaving a weak abdominal wall, with the danger of hernia. A cicatrix was left which was very apt to give way, and many patients had to wear a bandage. As to the fourth case, or one of acute gangrene, there should be but one opinion. He doubted whether an appendix, the seat of acute gangrene, ever got well without surgical interference. Here only an early operation would save life. In cases of the type of the fifth one there was again ground for a difference of opinion. If between attacks the general health was not what it should be, and especially if pain was becoming more severe, the indications for interference became more urgent. One could not always be sure of the diagnosis of appendicitis. He had seen errors in this respect. In the sixth case, also, if one could be sure of his diagnosis, an operation should always be performed. Left to itself the case, as shown by appearances at the operation, would have terminated in general peritonitis. But we could not always say that a perforation would not become hemmed in.

An Effectual Remedy.—DR. L. A. STIMSON thought there were many more risky operations undertaken for the relief of conditions of less severe nature than the one for which the operation discussed in the paper was undertaken, and the curative results were far from certain. It had been, and he supposed would long be, the custom to put up an imaginary individual who proposed to cut down upon every appendix which might become irritable, and to demolish him. He did not believe, however, that such an individual existed. He knew of no one who proposed to remove every appendix which might become inflamed. It was only proposed to remove the appendix in time. That proposition introduced an element of uncertainty. For the present we must bear with that uncertainty. He thought the risks of the operation had come to be better known than the risks of the condition for which it was a remedy. He heard of the cases which recovered, but not of the great many which died. Within a month he had learned of three in which death had taken place because of that peculiar failing—tendency to delay an operation. He thought it was better to have a soft spot in one's abdominal wall than a soft spot in the appendix, not to mention the liability to have no abdominal wall at all if an operation were not performed. A cure by medical means, when it took place, was, in the majority of instances, only an adjournment of the case. The cases in which we were in doubt were those in which the operation might perhaps be called for as urgently as those in which the indications were clear.

Distinction Between Appendicitis, Typhlitis, and Perityphlitis.—DR. A. JACOBI thought the indications for an operation would vary according to the tissues involved in inflammation near the cæcum, and that there were means of making a probable diagnosis aside from an exploratory incision. Inflammation in this neighborhood generally was characterized by suddenness of attack, by swelling, and by pain, yet the anatomical changes were not by any means always the same. In some cases we had to do with an affection of the appendix, such as had been described, in others with a typhlitis or inflammation of the cæcum proper, and in a third class of cases with disease in that neighborhood, or a perityphlitis. This meant phlegmon, or inflammation, and, frequently, suppuration of the loose connective tissue around the cæcum. These three conditions were frequently mistaken one for another. Yet, as a rule, appendicitis, or inflammation of the appendix from a foreign body or concretion within it, was not characterized by large swelling. For his own part, he should be in favor of cutting down just in those cases in which there was little swelling, but where other symptoms were prominent. The largest tumefactions were found early, not in appendicitis, but in typhlitis or perityphlitis, or connective-tissue inflammation and suppuration. In cases with large swelling occurring early he felt most inclined to wait, and try opium, the ice-bag, etc In connective-tissue inflammation the disease might be outside the peritoneal cavity, the appendix having nothing to do with it, and suppuration might be reached by simple incision. Yet, as in a large number of cases the diagnosis could not be accurately made, we were in doubt as to the propriety of an operation.

Why Appendicitis Occurs Oftenest in Children.—DR. JACOBI explained the greater frequency of primary attacks of appendicitis in children than in adults by the fact that the appendix was much larger in early life, and also by the fact that there was a valve like fold of the mucous membrane which prevented foreign bodies from getting out when they once entered. This fold gradually disappeared with years. Connective tissue about the cæcum was greater in the young also, which would account for the greater frequency of perityphlitis in them.

Dr. Jacobi also mentioned the practice of Sonnenberg, of Berlin, to make two operations in these cases, first to cut down to the peritoneum, then wait and see if pointing would not be induced to take place here.

Ten Months' Experience with Appendicitis.—DR. F. P. KINNICUTT read the following: During the past ten months, thirteen cases of appendicitis have come under my personal observation. Several of them I have had the opportunity of observing from the manifestation of the initial symptoms until either resolution occurred or surgical interference was practised. Nine were believed to be cases of catarrhal appendicitis, and a successful operation in six confirmed this opinion. In three, resolution, without operation, occurred. Three cases were of the perforative variety, in which perforation and a more or less gangrenous condition of the appendix was found. Two of these made an excellent recovery after operation. One case proved fatal, a general septic peritonitis being present thirty-six hours after the development of the initial symptoms. The thirteenth case was one of tubercular peritonitis. In one of the cases of the catarrhal form four well-marked attacks occurred under my observation during the above-mentioned period, the last a month since. In a second case, two attacks occurred in a period of three months, both also under my observation; in a third case, two attacks in four months; in a fourth, twelve attacks in twelve years; in a fifth, thirteen in two years; in a sixth, three attacks in four months; in a seventh case, eight in three years; in an eighth, three attacks occurred in one year. In the ninth case, the first attack occurred twelve years before operation; a second slighter one a year later. From this date there were frequent recurrences of paroxysms of pain, of short duration. During the three months before operation these were so frequent as to continuously disable him.

With a rather rapidly increasing experience, I have

ventured to formulate in my own mind certain impressions, an expression of which may serve as subjects for discussion and criticism. They may be summarized partially, as follows: The frequency of recurrent attacks in catarrhal appendicitis; the great probability of such recurrence when the physical signs, several weeks after an initial attack, reveal the presence of a small tumor, oftentimes no larger than the distal phalanx of the thumb; in the inguinal fossa, which points to the presence of an enlarged appendix, with thickened walls and adhesions of greater or less extent. In such cases a more or less frequent or constant sense of discomfort, varying much in degree, is experienced in the intervals of the attacks. My experience leads me to believe that medicine is without avail in such cases. and that eventually they must submit to operation for relief.

Another vivid impression that I have received concerns certain symptoms attending perforation, which I believe to be of practical import. With continued study of the symptoms of catarrhal appendicitis I am inclined to believe that a sense of discomfort or uneasiness in the region of the cæcum is very generally experienced, for a variable period of time, before the onset of the more pronounced and characteristic symptoms. On the contrary, in the perforative form the first symptom of the attack and of actual perforation is often agonizing pain, usually more or less localized, accompanied with vomiting, without elevation of temperature preceding or accompanying these symptoms, to be followed by a period of twenty-four or even forty-eight hours of deceptive calm, during which the patient is also apyretic or nearly so, this state to be again succeeded by a gradual rise of temperature, constitutional disturbance, and symptoms of a localized peritonitis, which may rapidly extend.

In conclusion I shall venture to express a personal opinion in regard to the initial treatment of attacks of appendicitis by means of laxatives, an opinion opposed to the practice of many physicians, and which I trust will be fully discussed. It is based on clinical experience and is that such treatment is unwise, if not distinctly harmful. In all cases of appendicitis, of whatever form, which have been under my personal care, or in which the treatment has been advised by me, opium has been given in doses sufficient to relieve pain and presumably to control intestinal peristalsis.

In the catarrhal form a movement of the bowels has been easily effected, and with benefit to the patient, at the expiration of three or four days by means of a simple enema. In the three cases of perforative appendicitis mentioned above, rather profuse purgation had been practised, previous to the time they came under my observation.

Appendicitis Usually Catarrhal.—Dr. Robert Abbe said the impression had been growing with him that to start with there was but one form of appendicitis, namely, the catarrhal. The cases in which the appendix or a portion of it was gangrenous had, according to his observation, given a history of previous attacks, leading him to believe there had been a catarrhal condition which had at last shut off the circulation and led to gangrene. He had seen no difference between cases occurring in children and in adults. It had been said that cases with numerous recurrences did not tend to suppurate, but he thought this was an error, and had seen two cases to support his view.

Period of Quiescence Delusive.—Dr. Abbe thought periods of quiescence during an attack had proven delusive to many physicians. They followed shutting off of pus by lymph, but repeated outbreaks with exacerbations of the symptoms might go on to take place, followed by quiescence, until a fatal peritonitis resulted.

Recovery after General Peritonitis.—He said that out of about thirty-seven cases of appendicitis operated upon by him the past three or four years, he could recall three or four in which recovery took place in spite of the fact that general suppurative peritonitis had already developed. Thorough irrigation was established by means of an opening in both loins. Therefore septic peritonitis following perforation was not necessarily fatal. Purgation should not be allowed, even in ordinary or mild cases of catarrhal appendicitis.

Where to Cut.—Dr. Arpad G. Gerster said that, although in Germany some surgeons operated even during shock in perforative appendicitis, he would prefer to wait until the patient rallied. In typhoid perforation he would operate at once. Regarding the danger of hernia, he thought this would be lessened by choosing, as could be done in some cases, the place for cutting; that is, cutting directly into the abscess and avoiding the necessity for building up a dam with iodoform gauze and resulting scar tissue. He congratulated Dr. Abbe on his success with cases of general suppurative peritonitis. He would hereafter try his method of very thorough irrigation, and would hope to save some of those patients which so far he had not done.

The Surgeon an Armament of the Doctor.—Dr. W. H. Draper had observed that the surgeons would throw the responsibility of diagnosis in inflammations in the region of the appendix upon the doctor. That was right—the doctor should bear the responsibility of upholding the dignity of the profession. He had always maintained that a good surgeon was in these days one of the most important armaments of the doctor. He was perfectly willing, then, that the responsibility of making a diagnosis and directing the operation to be made by the surgeon should remain with the doctor. But it was at times impossible to make an exact diagnosis of appendicitis, one chief reason being that the disease was frequently simulated by some other condition He had recently seen a case of supposed repeated attacks of appendicitis, so diagnosticated by doctor and surgeon; finally a surgeon cut down and found, not appendicitis, but salpingitis. In another case, operated upon by Dr. Bull, there was not appendicitis, but stricture of the ilium about twelve inches above the cæcum. There was, then, a great deal of difficulty in diagnosis, but where there was doubt in the minds of physician and surgeon an exploratory incision should be made.

Mild and Severe Cases.—The President thought the fact should be recognized that some patients who had appendicitis did get well under medical treatment alone and had no recurrence of the disease. This had been proven by post-mortem examinations. Further, it was not only true that complete recovery might take place but clinically some cases ran a mild course while others ran a severe one. The mildness or severity of the case was not always measured by the mildness or severity of the more palpable symptoms. The temperature and the pulse, for instance, might not tell the story. One had also to take into consideration the general aspect of the patient. By a sudden change in the appearance of a patient we could sometimes say that the appendix was perforated. Even though the preceding symptoms had been mild and none of the usual signs of collapse were present such a condition requires immediate surgical interference.

Primary Attacks Usually Mild.—From a considerable experience he had been led to believe that the first attack of appendicitis was usually a mild one, and that the patient was likely to recover under purely medical treatment. All severer cases usually gave the history of a previous attack, although the former attack, owing to its mildness, may have been overlooked. If in a given case the history, carefully inquired into, excluded former attacks, and the aspect of the patient did not point to a severe type of the disease, he thought the medical man would be perfectly safe in assuming the entire charge of the case. But as soon as he had reason to suspect sepsis or rapid extension of the disease surgical aid is demanded.

Illustrative Cases.—In a case of an acute primary appendicitis, when the temperature was high, the pulse very rapid, the localized tenderness very excessive, although little induration might be recognized, if the patient did not show signs of commencing recovery within forty-eight

hours a surgeon should be invited to see the case. Again, if in any acute appendicitis it was found that the area of induration was rapidly increasing and the temperature ran high the operation should be done at once. Even if such a patient should recover from his acute symptoms without an operation, a large area of induration would remain which would terminate in abscess and an operation. During his last service at Bellevue he had had three cases of acute appendicitis in persons who had had former attacks, and he urged an operation, but it was refused, yet they all so far recovered as to leave the hospital. These patients, however, are menaced by constant danger. In chronic appendicitis with occasional exacerbations, even if no induration is present, an operation is indicated lest a fatal exacerbation should occur when surgical aid could not be reached.

The Crowing Done by the Wrong Fellow.—Surgeons, the President went on to say, were pluming themselves for having been pioneers in the efficient treatment of appendicitis. In view of this it might not be out of place to say that as many as ten years ago he had made the statement before this Academy that the time would come when surgeons would be compelled to take more advanced steps in the treatment of appendicitis. He was glad to-day that they had taken them. In conclusion he stated that whenever both physician and surgeon were in doubt as to the diagnosis of any case, and the symptoms were sufficiently urgent, an exploratory operation should be performed.

That Double Operation.—Dr. McBurney said, in closing, that the double operation mentioned by Dr. Jacobi as practised by Sonnenberg was not new. It was introduced and practised in New York many years ago by the late Dr. Sands, and was highly valuable when in earlier days surgeons waited until the simple incision of Parker could be made. To-day it was unnecessary and harmful, for if the abscess were deep the primary incision could not determine it to the surface. It endangered the peritoneum, and when the second operation came to be made one might have to pass through septic tissue, which was a marked disadvantage.

Regarding Dr. Draper's humorous allusion to the relations of the surgeon to the physician, he said he was still willing to be the surgeon, as long as, like the eagle, the surgeon was the one to get the fish although to the fish-hawk belonged the credit of catching it.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 25, 1891.

H. P. Loomis, M.D., Vice-President, in the Chair.

Crural Hernia in the Fœtus. — Dr. Elizabeth M. Cushier presented an embryo of three months, showing a very marked crural hernia. In this case there was no possibility of its being the result of traumatism. The integument had been broken through, and the intestines lay upon the thigh of the embryo. Dr. Mary Putnam-Jacobi, who had seen the specimen, had called attention to the unusual shortness of the umbilical vein, and the displacement of the liver, and had suggested that the hernia was the result of this displacement. This seemed a rational explanation, as the pressure of the intestines in the lower part of the abdomen might have distended Poupart's ligament and the crural ring, which is so small in the embryo, and in this way have favored the protrusion of the intestine.

Crural hernia in the young subject was very rare; in six thousand cases quoted by Gerhardt no instance of such hernia was found in a child under one year of age. Dr. Cushier had been able to find only one example of this condition occurring in the fœtus, and that one was reported by Picquet in the Bulletin of the Anatomical Society of Paris, in 1846. That case bore a striking resemblance to the one just presented. The mass was in the left crural region instead of the right, as in the present case; the integument was intact, and the liver as well as the intestine protruded from the ring.

Abscess of the Brain Following Otitis Media.—Dr. H. N. Heineman presented specimens from the case. The patient, a man twenty-one years of age, and a printer by occupation, stated that his mother was a drunkard, and that he had been intemperate, and had often been without sufficient food. He did not indulge in tobacco, and he gave no history of specific disease. Eight years before coming under observation he had scarlet fever, and this was followed by middle-ear disease, and a discharge from the ear, which remained constant for five years, and then recurred about four times a year. These relapses were usually the result of exposure to cold during a debauch, and while they lasted he was often delirious. He was admitted to Mount Sinai Hospital on November 20th. One month prior to this, the ear began to discharge, and after a week of this he suddenly fell to the ground without a cry, frothed at the mouth, and was unconscious for a moment, with the pupils dilated and the facial muscles twitching. From this time on, he was delirious, frequently violent, and displayed a decided suicidal tendency. The temperature remained normal. Owing to his condition, there was no opportunity for observing the character of the gait. As there was only slight mastoid tenderness and no indications for immediate operation, the treatment consisted in keeping the ear clean by thorough irrigation. He died suddenly two days after admission. At the autopsy, the lungs were decidedly congested, but otherwise normal; the heart showed a diminution of the fat as the result of insufficient food during life; the liver, spleen, and kidneys were enlarged and congested, and the kidneys were of stony hardness and their capsules were not adherent. The stomach was small and contracted, and its mucous membrane thickened and coated with considerable muco-pus. The calvarium was normal, except that its inner surface was rather dry. The convolutions of the brain over the upper, lateral, and posterior portions were somewhat flattened, the pia mater was dry and lustreless, and its vessels were congested. On attempting to remove the brain, there was a sudden gush of pus from a cavity formed by the dura mater and pia mater. This abscess had destroyed fully four-fifths of the cerebellum. The dura mater over the petrous portion of the temporal bone was covered with a layer of fibrin and pus, but there were no evidences in this region of carious softening or of involvement of the bone itself. There was no pus along the vessels, and the meningitis was surprisingly limited.

Such a history of discharge from the ear, either constant or intermittent, associated with the slightest cerebral symptoms, even if not accompanied by an œdema of the mastoid region, furnishes snfficient grounds for immediate operation. Where the temperature ranges high—103° F. or 104° F.—a delay of even forty-eight hours will in most cases be sufficient for the meningitis to have progressed so far that operation is almost hopeless. Although it hardly seems warrantable to undertake an operation when there are only such few symptoms, it must be remembered that the decision of this question rests not upon the individual case, but upon experience at large, and the opinion just expressed finds abundant confirmation among aurists. The patient should be given the benefit of the doubt; if the operation be properly performed it does no harm, and it may be the means of saving life.

The bacteriological history of ear disease is not without interest. Friedlander's bacterium, Wechselbaum's coccus, Fränkel's pneumonia coccus are among the more important organisms which had been found in these cases. Some observers had claimed that where the streptococcus and the staphylococcus pyogenes aureus were present, further complications were indicated. It had been conceded by all observers that no conclusions could be drawn from simple microscopical examinations, but recourse must be had to cultures and inoculations.

During the past two years Rosenbach has found in the course of his bacteriological studies one case of chronic otitis in which streptococci and staphylococci were present, and another case in which he found a bacillus which has not yet received a name, but which is apparently responsible for the disagreeable odor characteristic of the discharge in these cases.

A Case of Appendicitis with Perinephritic and Subdiaphragmatic Abscesses, and Perforation through the Lung, was presented by Dr. J. S. Thacher. The patient died in St. Luke's Hospital immediately after admission, and this is all that is known of his history. About three weeks before he had pains in the right iliac region, with vomiting. When admitted to the hospital he had bloody and purulent expectoration. At the autopsy the vermiform appendix was found passing upward and backward behind the ascending colon to the region of the kidney, and for the greater part of its extent appeared normal, but the extremity was a little distended and about half an inch above the level of the umbilicus it opened into an abscess about the kidney. This abscess reached upward from a level about one inch below the umbilicus, along the front of the kidney, to the under surface of the liver; from here some sinuses led behind the liver to a large abscess between the liver and diaphragm, which contained about a quart of pus. From this cavity a small perforation through the diaphragm opened into the substance of the lung, the pleura at the base being adherent.

In connection with this case, Dr. Thacher also reported a somewhat similar case, on which he had made an autopsy several years ago. The patient, who was seventeen years of age, was treated in the Emigrant Hospital on Ward's Island, and the diagnosis was pneumo-hydro-thorax of unknown origin. The autopsy showed a perforation of the vermiform appendix. A small, hard piece of fæces, somewhat resembling a cherry stone, was found just outside the appendix in the iliac fossa; there was black, gangrenous, foul-smelling inflammation running up from this point along the kidney to the back of the liver, then to the vertebral column, and along this into the chest. The right pleural cavity contained a large quantity of thick pus with a very bad odor.

Dr. Heineman said that these specimens were always of great interest. The condition just described was generally looked upon as a rare complication, but he had personally met with not less than six or eight cases where a perityphlitic abscess had perforated into the pleural cavity, causing empyema and death. With our present clearer knowledge of perityphlitic abscesses, it seemed hard to believe that, not many years ago, even experienced and careful observers always expected them to point anteriorly, and if a tumor formed in this region posteriorly one of the last conditions thought of was perityphlitic abscess. For example, a woman came into the Roosevelt Hospital with a tumor pointing backward, and although seen by many of the visiting staff, no one suspected perityphlitic abscess. The cavity was incised and washed out, after which new sinuses kept constantly forming, and for a period of six years she gave the house-staff ample opportunity of becoming acquainted with the treatment of such sinuses. Finally, the prolonged suppuration caused waxy degeneration, and the patient died in 1871. He had presented the specimens to this Society in 1878. They showed that originally she had suffered from a perityphlitic abscess.

Primary Cancer of the Bladder.—Dr. H. P. Loomis presented specimens of the above. The patient, Joseph D——, forty-seven years of age, was perfectly well up to four years ago, when he began to have renal colic accompanied by frequent and painful micturition with bloody urine. During these attacks, which lasted from four to eight days, he would pass small calculi, following which all symptoms disappeared, and he would be as well as ever for three or four months. Then would come a repetition of the trouble. The last attack occurred four days prior to his admission to Bellevue Hospital. The urine was then scanty, but the desire to urinate occurred every fifteen or twenty minutes, and after straining he would only pass a small quantity of blood containing a few clots. The diagnosis lay between stone in the bladder and a tumor. The majority of those who saw the case inclined to the latter. An examination of the bladder by a "searcher" gave negative results, for the organ was firmly contracted, and a large clot seemed to interfere with the manipulation of the instrument. On the third day after admission the patient became comatose, and died within twelve hours. At the time of making the autopsy, twenty hours after death, all the organs were found to be normal with the exception of the bladder and kidneys, which presented the following appearance: The bladder contained a fungoid mass, three and one-half inches in diameter, projecting from the posterior wall just above and around the left ureter. Its surface was ulcerated. A half-dozen hard nodules, varying in size from a pea to a small cherry, were scattered over the wall of the bladder. The walls of the bladder were hypertrophied, and hardly any normal mucous membrane could be found. There were no blood-clots or stones in the bladder. The left ureter was dilated to twice the size of a pencil, and its wall was very much thickened. The left kidney was of normal size, but on section hardly any kidney substance was found, its place being taken by a number of cavities communicating with the dilated pelvis of the organ. The cavities and pelvis contained a muggy yellow fluid, but no calculi. The right ureter was slightly dilated, and the right kidney somewhat enlarged. A microscopical examination of the organ showed a moderate amount of chronic diffuse nephritis, with intense congestion, and in places cloudy swelling.

Primary tumors of the bladder are of rare occurrence, although frequently the organ is involved secondarily, especially by extension from the uterus or rectum. The most common of the primary growths here is the "villous tumor" Ziegel says, "primary cancer of the bladder is of exceedingly rare occurrence." Besides the infrequency of this condition, the specimen was of interest as showing the difficulty in differentiating this condition from "stone," especially when the history of passing stones is as clear as in the present case. The stones passed by this patient during the last two years were repeatedly examined by the attending physician, yet none were found in the bladder or kidneys. The question naturally arises, was there a connection between the gravel and the cancerous development? Although the bladder-symptoms dated back four years, it is not possible to conceive of cancer of the bladder lasting over this period. The condition of the left kidney was unquestionably due to hydro-nephrosis, the growth in the bladder partially occluding the orifice of the left ureter. Undoubtedly the right kidney had for a long time kept up the excretion of the urine. Suddenly an acute nephritis was developed, and uræmic coma and death were the result.

Dr. H. S. Stearns remarked that about one year ago he had presented to the Society a very similar case, in which there was a primary cancer with colloid degeneration, but with no history of calculi.

Perforating Ulcer of the Vermiform Appendix.—Dr. Loomis also presented a specimen of the above. The patient, a boy thirteen years of age, showed the ordinary symptoms of appendicitis for six days, when general peritonitis suddenly supervened, and he died within twenty-four hours. At the autopsy there were the usual signs of peritonitis. In the right iliac fossa was a circumscribed abscess containing about half a pint of foul-smelling pus, and a round, hard pellet of fecal matter, the size of a cherry, in which no foreign body could be found. The appendix was as large as a lead pencil, measured three and one-half inches in length, was non-adherent, and covered by a recent exudation of lymph. An inch from its free extremity was a ragged

opening large enough to admit the tip of the little finger; the end of the appendix was almost detached, and was only joined to the main portion by bands of necrotic tissue. The case was interesting, as undoubtedly early surgical interference would have saved his life. Dr. Loomis said that he was indebted to Dr. W. H. Haynes for the specimen.

The Society then went into executive session.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 21, 1892.

S. B. W. McLEOD, PRESIDENT, IN THE CHAIR.

Recent Investigations Relating to the Prevention of Diphtheria and Scarlet Fever.—DR. J. LEWIS SMITH read a paper on this subject. Prophylactic measures which were appropriate for diphtheria were for the most part also appropriate for scarlet fever, and for this reason he considered methods of prevention of the two diseases in one paper. To properly employ prophylactic measures one should consider the etiology and pathology. Scarlet fever was believed to be of microbic origin, although, unlike in diphtheria, bacteriologists had not agreed as to the specific microbe which caused it. The poison was tenacious of life, and easily communicable. It was often carried to a distance in clothing, etc. He had thought that in New York a frequent means of transportation was in school-books which the sick had handled in bed. Certain germs, including the streptococcus of Rosenbach, had been found in numbers upon the fauces, and it was not unlikely they had to do with the causation of the disease. At any rate, in scarlet fever there were facts pointing to the desirability of early applications of germicides to the fauces and nares in order that complications might not arise which often were more fatal than the original disease.

In diphtheria the theory that the cause lay in the Klebs-Löffler bacillus had come to be commonly accepted by bacteriologists. The bacilli were found in abundance in the pseudo-membrane and on the surrounding surface. It remained localized, while the poison which it produced entered the circulation and caused constitutional symptoms. The poison introduced into the circulation of rabbits and dogs caused paralysis similar to that seen in diphtheria. It had been said that there was a micro organism similar to that of the Klebs Löffler, but deprived of the virulence of the latter, and that this virulence might be assumed by it under certain favorable conditions of air, etc. There were some who stated that there was a pseudo-membranous inflammation or necrosis in scarlet fever similar to that seen in diphtheria, yet not due to the Klebs-Löffler bacillus.

A French writer had called attention to the fact that there were other micro-organisms, as the staphylococcus and streptococcus, which might cause poisons enhancing the systemic effect produced by the Klebs Löffler in diphtheria. These organisms might occur not only on the pseudo-membranous surface, but also in the interior of the body, while the Klebs-Löffler remained local. The latter germs were very long lived under favorable conditions.

While the most common mode of contracting diphtheria was by contact with the sick or infected articles, yet Dr. Sternberg had called attention to the fact that damp cellars and places where there was sewer-gas were favorite abodes of the disease. Dr. Smith believed that not an uncommon mode of spreading diphtheria was by "walking" cases. He had had a number of cases brought to his out door clinic at Bellevue Hospital.

He said, regarding the efficacy of attempts to prevent spread of diphtheria, that Baker had found a smaller average number of cases when attempts at preventing its spread during outbreaks were made than when no attempts were made. Granger, of Paris, had charge of wards for diphtheria into which during a number of years a large number of children had been admitted who had not diphtheria, yet none of them had contracted the disease. The precautions taken by him consisted in surrounding the bed with a metallic screen, use of heat for sterilizing clothes, of a solution of corrosive sublimate. For cleansing purposes nurses wore a blouse which was disinfected every day. Similar precautions were recommended by Dr. Smith in private practice. The doctor should put on a blouse or a sheet on entering the sick-room. He should stand behind or at the side of the patient while making an examination; or a pane of glass might intervene between doctor and patient during inspection of the throat. The hands, face, and beard should be washed with a solution of corrosive sublimate. Pictures, curtains, etc., should be removed from the room. Before sending healthy children away have them bathed in an antiseptic solution, put on clean clothes, and spray the fauces with a mixture of one part of peroxide of hydrogen to three of water, and the nostrils with one part to six. The physician should avoid other children for an hour or two after his visit. It would be well if the bedstead, floor, and walls of the room were washed every day with a solution of corrosive sublimate, as recommended by Grancher. Dr. Smith also prescribed the following disinfectant, which he believed to be useful in preventing the spread of the disease, and the occurrence of nervous sequelæ: Oil of eucalyptus, one ounce; carbolic acid, one ounce; turpentine, eight ounces; mix in a bottle. Add two teaspoonfuls to one quart of water, and allow to simmer near the patient constantly. He used this in scarlet fever also. The following was recommended for inunction in scarlet fever: oil of eucalyptus, one drachm, carbolic acid, one drachm; sweet oil, seven ounces; shake well, and apply to the entire surface every three hours.

Reference was made to Dr. Caillé's suggestion that the throats of school children be examined by doctors every day, each child using its own fingers for a spatula. Some doubt had been expressed as to the value of sulphur fumigation of rooms at the termination of diphtheria, etc. Dr. E. R. Squibb had stated that it was more effectual if the sulphur were burned over a receptacle containing water, or if the room contained aqueous vapor. It was better to wash the bedstead and floor with a solution of corrosive sublimate, and paint or whitewash the walls and ceiling.

The Most Beneficent Work of Man.—DR. C. A. LEALE thought that the most beneficent work of man was the prevention of disease. To him no disease was so alarming as diphtheria, not excepting small-pox. He related some experience, showing its terrible malignancy. He believed it was due to a specific germ, and that without this germ diphtheria could not arise. The difficulty of destroying the seed might be imagined when one recalled the fact that grains of wheat hundreds or thousands of years old had grown when put in a suitable soil. Further, consider the favorable conditions existing in this city for the propagation of diphtheria. In the rounds of charity work physicians had found as many as four families in a room not more than twenty feet square, the space occupied by each family being marked off by a chalk line. We had not room for the crowds of immigrants now coming over.

Regarding sulphur fumigation, he had found it most efficacious when combined with moisture. He mentioned one or two points in treatment, and said that he thought the less one interfered with the excretory organs, as by inunction of the skin in scarlet fever, the better it would be. Water was about all that was needed in a simple case. In diphtheria, acids, especially lemon-juice, were very efficacious.

Be Less Sympathetic with the Public.—DR. HENRY KOPLIK thought physicians would be justified in being less sympathetic with the public in their efforts to prevent

disease. What might be looked upon as severe measures were allowed for stamping out typhus fever, while great indifference was shown in scarlet fever and diphtheria, which often were more serious affections. We should advocate for those exposed, or liable to be exposed to these diseases, *maisons de santé*, or places of refuge.

Dr. Leale remarked concerning this point that there would not be hospitals enough in all New York to accommodate those exposed to diphtheria and scarlet fever.

A New Bandage.—Dr. Daniel Brown demonstrated a new, but not original, mode of applying a bandage to take the place of a roller bandage when for any reason this was not best, or could not be applied. The arm, for instance, was wrapped with cotton, or, if required, a splint was applied, and then a single or double piece of cheesecloth was sewed on. Wherever too loose, extra rows of stitches were inserted.

Correspondence.

OUR BERLIN LETTER.

TUBERCULOCIDIN—AN IMPORTANT DISCOVERY BY KITASATO—DIPHTHERIA DEBATE IN THE BERLIN MEDICAL SOCIETY—CONGRESS OF BALNEOLOGY.

Berlin, March 13, 1892.

Tuberculin is dead—long live tuberculocidin. This is the label of the new era, by one of the oldest and most renowned antagonists of Robert Koch—Edwin Klebs, in Zürich.

Professor Klebs published an article in the *Deutsch. Med. Wochenschrift*, about the end of last year, claiming that he could isolate from the raw tuberculin its active principle.

This he did by treating this tuberculin with the alkaloid reagents, and found an albumose which precipitated with alcohol. This substance, he claimed, contained the healing properties of the tuberculin without its previous dangerous contamination, and named it tuberculocidin or alexin.

In a publication which has just appeared, entitled the "Treatment of Tuberculosis by Tuberculocidin," Hamburg and Leipzig, 1882, Leopold von Klebs gives his therapeutical results of animals previously infected with tuberculosis, and also on human beings who contracted tuberculosis.

Klebs calls attention to the fact that during the treatment there is a considerable shrinkage and even utter disappearance of the tuberculous (previous) tissue.

Macroscopically nothing tuberculous could be found; microscopically, however, the remnants of tuberculous tissue could be identified, and in these latter fragments the bacillus tuberculosis had entirely disappeared.

This cure resulted after 25 daily injections of 1 ctgr. to 500 gm. body-weight in cases that were tuberculous about six weeks.

This dose, reckoned or estimated according to the body-weight, would be equivalent to 1 to 1.2 c.c. daily of tuberculocidin. Some patients can bear still greater doses than this. It would therefore take to cure a case of tuberculosis about twenty-five to fifty centigrammes of tuberculocidin. In milder cases we can attain the same result with smaller doses.

Until now Klebs has carefully watched 75 cases. He regards as completely cured 14, which equals 18.6 per cent. of all cases. Improvement in 45 = 60 per cent., under; not improved he has 14 = 18.6 per cent., and 2 deaths = 2.6 per cent.

All cases recorded in the above statistics are cases of severe and positively typical cases of pulmonary tuberculosis. Among the cured cases of Klebs there are cases of beginning meningeal tuberculosis and also cases of miliary tuberculosis. This proves that tuberculocidin is entirely different from tuberculin, inasmuch as it does not produce necrosis of the tissues and does not increase and scatter tubercle bacilli to different parts of the body as does tuberculin.

The author considers his treatment especially valuable, because his patients do not undergo a high feverish crisis, but can be treated as out-patients (ambulatorisch). The author furthermore does not desire by his method to suppress all pre-existing remedies. But he believes that it can eventually be a universally popular remedy if all additional care be added to it. At present it is very expensive, costing ten marks for 1 c.c. of one hundred per cent. tuberculocidin, but it will be cheaper later. The instructions which Klebs gives with his remedy are to commence with two to five milligrammes; if there is no reaction, or no severe reaction, to increase the dose very rapidly.

Hectic fever is no contra-indication for its use, but care must be had that the morning temperature does not rise very high. The dose can be raised rapidly to 1 ctgr. and then to 2 to 4 to 8 ctgr. The real treating dose for a person is 1.0 to 1.5 dcgr., divided into single injections of 5 c.c. of the undiluted substance. During the treatment the pulse, temperature, weight, several constitutional conditions, and appearance should be carefully noted.

After a period of four weeks a second series of injections can be commenced if the indications warrant same.

We have given a *résumé* of Klebs' announcement and sketched the details of his treatment. To criticise now would be too soon. We can, however, say that it seems to me as though Klebs has advantages which Koch did not have. Being in a small city (away from a million of people, as Koch had) he has more control and can command and watch his patients easier and have them much longer under observation, and, above all, he will be positive of not having a rush for treatment at least for some time, as Koch had.

Another advantage is the fact that Klebs lives near Davos, a prominent resort (winter resort) for phthisical patients. It would be welcome if Koch's discovery would at least find its scientific value, although post festum, through this new modification.

Although the tuberculin treatment in our hospitals has been, so to speak, abandoned, there is still considerable work done with the cause of tuberculosis—namely, its bacillus.

For one of the most prominent bacteriologists, the Japanese Dr. Kitasato has succeeded in producing the tubercle bacillus in pure culture from the sputum. Heretofore it needed the intervention of the guinea-pig, and then it could not be positive. Koch announced a simple method, which Kitasato has applied practically. It consists in procuring flakes of sputum from the deep respiratory tract, isolating some and washing some in about ten glasses containing sterilized water successively.

If then the sputum is torn or broken up in the last saucer (containing this sterilized water) we can easily tell if it contains tubercle bacilli or not. We can in this way take a small particle, and by inoculating blood serum or glycerine-agar easily procure a clear culture of the bacillus, if present.

Kitasato has furthermore found that in closed pulmonary cavities there existed besides tubercle bacilli a clear culture of another species of bacteria. What importance or relationship the latter bears to tuberculosis, if any, has not yet been proven.

At the same time he found that all tubercle bacilli found in pulmonary cavities were dead. It was proven that agar tubes inoculated with same remained perfectly sterile. At the same time he could, after a few weeks, take and stain good-shaped bacilli from the point of inoculation on agar.

Guinea-pigs inoculated herewith remained perfectly healthy. From this we can make the following important deduction, viz.:

That although we can have tubercle bacilli in a tissue and prove them by a staining process, it does not follow that these same bacilli can reproduce themelves or

that they must be living. What importance this will have for the tubercle bacillus, viewing it from a biological standpoint, remains to be seen.

This important discovery is mingled with the fact that Dr. Kitasato will retire from his present position as assistant at the Institute for Infectious Diseases here in Berlin, to be honored by the position of Director of the Hygienic Institute just erected by the Japanese Government for bacteriological studies.

After tuberculosis, with the exception probably of the influenza, most importance and interest is at present centred in the diphtheria question, and it is here the much less known diphtheria bacillus exerts an important bearing on the prophylaxis and treatment of diphtheria.

One of our most prominent pediatrists, Dr. Adolph Baginsky, recently read a paper, with demonstrations, on "The Etiology of Diphtheria," before the Berlin Medical Society.

Baginsky tried to solve the question: 1, Whether the Löffler's bacillus was present in all genuine, severe attacks of diphtheria, and, 2, is there any relationship between the presence of the bacillus and the way in which the disease manifests itself? This Baginsky claims by investigation to answer affirmatively.

According to Baginsky there are two kinds of diphtheria, with membranous manifestations in the pharynx, which, according to the severity or the mildness of the attack, can be differentiated.

In the first we always have the presence of the bacillus, and which he regards as genuine diphtheria.

In the second, the bacillus is always absent, and is a relatively mild disease.

This question can be easily settled by a simple bacteriological examination of the membrane and the positive or negative presence of the Löffler's bacillus determined, and thereby the pathogenic character of the disease determined. This standpoint, as simple as it appears, has its drawbacks, as appeared during the discussion.

Dr. Troje (formerly assistant to Professor Baumgarten in Tübingen) called attention to the fact, that although a culture might prove the possibility of the presence of the Löffler's bacillus, yet to positively determine the presence and differentiate the Löffler's bacillus from other schmarozern in the pharynx, *e.g.*, the pseudo-diphtheria bacillus, there could be but one method, and that is animal experiment or inoculation with the supposed pathogenic culture.

As Dr. Baginsky did not use animal experimentation in all cases which he cited, so a considerable weight is lost thereby, and his deductions are not regarded with that same positiveness as otherwise. In this same strain others that took an active part in the discussion followed. There still remains some distinct clinical and practical criterion with which to positively diagnosticate cases of supposed diphtheria, and here is where we have a desideratum.

From this high and important question of the day, and painful question, let me step down to the meeting of the Society of Balneologists, which met on the 10th of this month (fourteenth meeting) under the presidency of Professor Liebreich.

Between beer and sandwiches we have sometimes heard the settlement of many difficult scientific problems in a sociable manner.

Especial mention should be made of a paper read by Dr. Weissenburg Colberg entitled "The Treatment of Gastric Neuroses," in which a very active discussion followed by Professor Ewald and Dr. Boas; "Treatment of Eczema," by Dr. Lassar; "Our Present Standpoint in the Diabetes Question" (referant, Dr. Jacques Mayer, in Karlsbad); "The Treatment of Tuberculosis by Koch's Method," by Dr. Römpler, in Görbersdorf—a paper, by the way, which had no discussion, and for this latter reason pleased everybody present. Lastly may be mentioned a paper read by Dr. Posner, of Berlin, entitled "The Treatment of Excessive Uric Acid Formation," with some other papers of minor importance. As the constitution and by-laws of this society call for sociable meetings after the scientific part is terminated, so there was accordingly a banquet, with ladies attended by scientists and physicians (not necessarily all members of this Balneological Society), also their relatives and friends. This was especially well attended this year.

SUPERNUMERARY MAMMÆ.

To the Editor of the Medical Record.

Sir: In your issue of October 10, 1891, I contributed Case IV. (Fig. 5), to Dr. McGillicuddy's paper on "The Mammæ and their Anomalies." I feel constrained, therefore, to answer Dr. Williams's criticism on this case, published February 13, 1892.

The doctor objects to the identity of this supernumerary mammary gland because 1, of its situation; 2, that it has not been adorned with an areola; and 3, nipple. Ergo, lacking these requisites (?) it should not be accepted without more conclusive evidence. Let us see, "when we speak of a part as anomalous we mean that it varies *at birth* from the ordinary or typical form."

1. It is absurd to dispute the genuineness of the gland on the grounds of its situation, because illustrations are too numerous in the "prodigious literature of the subject" to deny the possibility of a mammæ existing on any external part of the body where glandular tissue (elements) may develop.

And because its relation to the normal gland is so intimate that there may be an anatomical connection (as exemplified in Case II., Fig. 4) between the two, which is impossible to define, or determine, owing to the patient's unusual pectoral development.

I related the case to Dr. McGillicuddy and some particulars were purposely omitted.

2. The growth has existed since infancy. By titillation the gland enlarges, a faint pinkish circle, one quarter inch in width, is exhibited, enclosing about a dozen follicles, forming a rugosity easily perceptible to the finger and clearly defined by a pocket microscope that I habitually carry. External to this areola are four or five strong, curly, brown hairs, corresponding to those found on each of her bona fide breasts. These points were well brought out in the photograph from which the cut is taken.

3. There was no well-defined nipple. This deficiency is of no importance, and detracts in nowise from my argument.

The growth was examined by three competent surgeons, who agreed that its structure was analogous to the rudimentary mammæ found in the immature of both sexes and the unmarried adult female.

The paper was read before a medical association numbering over seven hundred members, and not one word of adverse comment was made during its discussion. I believe my position sustained, and wish to remind my critic that there is more in heaven and earth than is dreamed of in his "polynestism."

M. C. O'Brien, M.D.

161 West 122d Street.

To the Editor of the Medical Record.

Sir: In your issue of February 13th, Dr. W. Rogers Williams, F.R.C.S. Eng., takes me to task for not being more prolix in my description of the cases of mammæ erraticæ, published last October. He says that several of my cases are so bizarre and unprecedented that they should not be definitely accepted without most conclusive proof as to their real nature. If the doctor will please state what more proof he desires, that can be obtained without a surgical operation, I shall be glad to satisfy him. Of the six cases that could in any way be questioned on account of their unusual location three of these had milk exuding from them, so I think that alone sufficient proof

of their glandular structure; so his several cases have become three, of which he specifies Cases IV. and VI. Case IV. (Fig. 5), sent me by Dr. O'Brien, has an areola, and she has had pain in all three glands during her menstrual periods, and "two years ago all the mammæ increased in size simultaneously." In Case VI. (Fig. 7), the other case he objects to, I should like to ask him what else it resembles. Yourself, Mr. Editor, having seen the original photograph, will say that the illustration by your own artist is a perfect copy of it. It is exactly the same shape, and as large as the normal breast of a young woman, and its lobular structure can be distinctly determined on manipulation. It has a nipple, and on its surface are seen large blue veins. This individual has been for years in an asylum where there is a staff of about twenty resident physicians, who change frequently, besides others visiting, and his case has never been doubted.

In regard to their unusual location I find from cases reported that, contrary to Dr. Williams's idea, hardly any portion of the body is exempt except the hands and feet, and within two months I have seen a case where there is a perfect nipple and areola at the outer border of the left glutæus-maximus muscle in a woman aged forty.

All the cases reported, with one exception, were brought to my attention by other physicians, and the majority of them have been exhibited before some of the New York Medical Societies. F. J. McGillicuddy, M.D.

776 Madison Avenue.

THE DISPENSARY QUESTION.

To the Editor of the Medical Record.

Sir: In 1850 New York City had a population of 422 480, and the number of physicians, practising or otherwise, was 400. In 1890 the population was 1,624,418, and the number of physicians 3,276, so that since 1850 the population had increased four times, whereas the medical fraternity had increased itself eight times. If the doctor was paid as well in the days of 1850 as now, with proportionately fewer and less ample dispensaries and hospitals than to-day, the occupation of the average doctor must have been much more lucrative then than at present. The development of special departments of medicine no doubt has done a great deal to increase the doctor's income. Since 1850, gynæcology, laryngology, dermatology, ophthalmology, otology, neurology, orthopædic, and some other special branches of surgery have made great strides, so that the field has been very much widened.

So far as the evil of dispensary abuse is concerned there is no doubt that there are many impositions. Yet it has been observed that a great many in moderate circumstances go to the dispensaries, not merely for the free service obtainable but because the service is much more skilled than they often obtain by even paying for it. On inquiry many had already been attended in private before coming to the dispensary, and, either because their money was exhausted or they were losing patience with their medical adviser, the dispensary was resorted to. Hence in this way the evil frequently originates. Finding they often obtain better results by consulting experts in the special branches of medicine at the dispensary, there is much stronger inducement to go to the dispensary than to the physician in private.

Another factor to be observed is, that a great many patients having trivial complaints who go to the dispensaries would not go anywhere if they had to pay for the advice. Veritas.

New York, April 2, 1892.

THE MODERN GREEK LANGUAGE.

To the Editor of the Medical Record.

Sir: In an editorial of your issue of March 19, 1892, you suggest that the Greek language be adopted as the universal language for scientists. Indeed, the idea is a happy one. It would not only facilitate intercourse at the international congresses, but it would elevate the profession if every physician would be able to express himself in Greek. I agree with you in almost all what you say about the advantages of the Greek over the Latin, its being more flexible and more beautiful, equally clear and expressive, and at the same time much better adapted for use as a conversational tongue. But when you say "the modern form of the language, such as is in use in Athens to day, is easily learned," I beg to differ with you.

The real, new Greek is the vulgar, the every-day conversational language used by everybody, taught nowhere, spoken by all, exactly as the dialects in Switzerland. This vulgar Greek is called Ῥωμαΐκα, in contrast to Ἑλληνικά, the literary or old Greek. This latter is the written language, the language of the journals, the books. Whoever will become familiar with the Ἑλληνικά has to learn old Greek, because the vocabulary and the grammar are essentially old Greek. Ῥωμαΐκα is the conversational language, not only in free Greece but also is it the principal language of commerce and every day intercourse in the Levant. It is spoken in Macedonia, Roumelia, Constantinople, Smyrna, Trebizond, on the coasts of Asia Minor, on the islands of Archipelagoes, even in Alexandria and Cairo. For the traveller and business man in those countries it is important to undersand it.

The more educated a man is, the more the subject of the conversation is above the every-day business matters, the more the Ἑλληνικά will be made use of. Ῥωμαΐκα is found in literature exactly as we have Swiss and some German dialects in literature, namely in witty journals, in novels, comedies and poems.

Before me I have, through your kindness, a number of a Greek medical journal, dated Athens, February 8, 1892, the title is Γαληνός. It gave me great pleasure to read this publication, and I conceive, in perusing it, that anybody who has learned old Greek is able to understand the new Greek literature without having to study expressly again.

As everybody knows, the pronunciation, as it is taught in most schools, differs from the pronunciation of modern literary Greek, but this could easily be remedied. As a matter of course, the language to be adopted by scientists, would have to be Ἑλληνικά and not Ῥωμαΐκα, and I suppose you will agree with me in this.

Our German poet, Heine, when he went to school in Düsseldorf, used to pass daily in one of the corridors of the school building a life size crucifix. Observing the expression of pain on the face of the image, in his childish ideas he said, "Poor Christ, you no doubt suffered like myself very much when you had to learn the Greek irregular verbs!"

Another German schoolboy distinguished the regular from the irregular Greek verbs, saying that they got more thrashing in learning the latter than in learning the former.

If you really think that the Greek, as it is spoken in Athens, be it the vulgar or the language of the educated class, is easy to learn, I presume you mean for anybody who understands or has learned old Greek in school, otherwise you will find very few among those who have learned Greek in school to agree with you.

Ῥωμαΐκα, although it has become mixed with many foreign words during the long periods of servitude, is a genuine legitimate daughter of the classical Greek. Who understands the classical or the modern literary Greek has indeed no difficulty in learning the vulgar Greek.

Most respectfully yours,

A. Rose, M.D.

[We did not mean that ancient Greek, as taught in our schools and colleges to-day, is easy to learn, but that is the fault of the antiquated and senseless methods of instruction rather than of the language itself. Modern Greek, Νεοελληνικὰ, although not differing materially from the old tongue, is yet somewhat easier in its construction, and, when taught according to the modern conversational methods, is not one whit more difficult to learn than French or German, even for one who has never studied the classical language.—Ed.]

A CONTRIBUTION TO THE STUDY OF BULBAR PARALYSIS.[1]

BY HERMAN H. HOPPE, M.D.,

CINCINNATI, O.,

ASSISTANT TO THE POLIKLINIK AND LABORATORY OF DR. OPPENHEIM IN BERLIN.

ALTHOUGH great progress has been made in the last two decades in general pathology, and especially in the pathology of the central nervous system, there are many points which are still dark and wait for an explanation. Not only is this true of the minute microscopic changes, but even of those which are of a grosser nature.

Partly through clinical experience, partly as a result of experimental physiology, we are accustomed and justified to look upon the development of certain symptoms and classical clinical pictures as being due to pathological changes in certain organs of the body, but although we can say with a certain degree of certainty, that this or that complex of symptoms is due to a change in this or that organ, experience at the post-mortem table or in the laboratory shows us that there are many exceptions to the rule. Such mistakes are especially apt to occur in the field of neurology, where the neuroses so often present the picture of an organic disease and thus cause difficulties of diagnosis. The opposite is equally true: the previous history of the case, the subjective symptoms, the objective signs, the entire aspect of the patient, all point to a functional trouble, and the post-mortem examination shows pathological changes which have caused the clinical symptoms.

Thus Charcot describes a case in which he had made the diagnosis of hysteria during life, but which after death proved to be a lateral sclerosis. Westphal, who had occasion to observe two cases of general neuroses, which during life presented the clinical picture of multiple sclerosis, was unable to find any pathological changes whatsoever at the post-mortem examination, and maintained "that there exists a general neurosis, which, neither by its symptoms nor by its course, shows any marked deviation from the complex of symptoms most frequently observed in multiple sclerosis."

Coming back from pathology in general to the special pathology of bulbar paralysis, we can say that the anatomical changes explain the clinical symptoms. Opposed to the clinical picture produced by a loss of function, and an atrophy of the muscles in the regions supplied by the hypo-glossus, facial, glosso-pharyngeal, accessorius, trigeminus, and vagus, we find an atrophy, more or less marked, of the corresponding nuclei and roots of these nerves in the gray matter of the bridge and medulla oblongata, and a sclerosis of the pyramidal tracts. And yet we find, not so rarely, that the loss of function of this or that nerve, even in the very chronic and progressive cases of Duchenne's disease, cannot be explained by a corresponding atrophy of its nucleus. Thus Charcot[2] found in a case in which the clinical symptoms of a bulbar-paralysis were highly developed, a well-marked degeneration of the hypoglossal centre, no change at all in the glosso-pharyngeal centre, and only a slight pigmentation of the otherwise normal cells of the nuclei, of the facial, vagus and motoric trigeminus, which to-day is no longer looked upon as an evidence of beginning atrophy. The pyramidal tracts, however, showed marked degeneration.

Eisenlohr,[1] in 1880, reported two cases of bulbar paralysis; in the one, an atrophy of the nucleus of the vagus accessorius could not be found, while the other centres in the floor of the fourth ventricle were markedly atrophic. In the second case the hypoglossal and vagus accessorius centres were atrophic; the vagus and glossopharyngeus showed no changes whatever, while the ganglionic cells of the facial and abducens centres showed only a slight pigmentation.

Similar observations have been made by Freund,[2] Thomsen, and others. On the whole, however, we can say that the anatomical changes found in chronic progressive bulbar-paralysis are constant, and consist either of a simple atrophy of the nuclei in the gray matter of the floor of the fourth ventricle, or, what is more frequent, a combination of an atrophy of these centres with a sclerosis of the pyramidal tracts. Cases have, however, been reported, three in number as far as I have been able to ascertain, which by their complex of symptoms, as well as by their course, duration, and termination, show a close relationship to the Duchenne form of bulbar paralysis, in which the most careful anatomical examination was unable to reveal any changes in the corresponding centres of the medulla oblongata, or any pathological changes whatsoever.

The case which I am about to report belongs to this category. The clinical observations and examinations were made by Oppenheim:

Herman H——, aged forty, was received at the Royal Charitè on March 25, 1889. Previous history: Parents died of diseases unknown to patient. Has six sisters, who are alive and healthy. Patient has been married for five years; has no children. Denies syphilis. States that he has never been sick before. Since his twenty-eighth year he has suffered from buzzing in the ears, which first began in the left ear and soon after in the right. At no time has there been any pain in or discharge from the ears.

Present disease began three weeks ago with difficulty of deglutition, which has gradually increased; patient noticed at the same time that he had no taste and "no power in his mouth," that is, he was unable to masticate his food well. Speech was accomplished by a nasal twang, and the words were not articulated sharply. Besides this, both eyelids began to hang down lower than usual and patient could raise them only with difficulty. He also complains of profuse night-sweats and of a bad taste in his mouth when he arises in the morning. Sleep is somewhat restless; bowels are constipated. No difficulty of micturition. Appetite is good. Has no other complaints. The development of the disease has been gradual and painless and the symptoms arose in the order given above: the difficulty of deglutition set in first, a few days afterward the eyes became affected, and the disturbance of speech two days later.

Present Condition.—Patient is tall, pale, and somewhat emaciated. The well-marked longitudinal furrows of the forehead and the sinking down of the eyelids give the face a peculiar expression. On the right side the ptosis is complete, on the left side the upper lid hangs down so far as to cover the upper fourth of the pupil. Patient is able to raise the upper lids a trifle if he makes

[1] A paper read before the Berliner Verein für Psychiatrie und Nervenkrankheiten.

[2] Charcot: Archive de Physiologie. 1870.

[1] Zeitschrift für klinische Medicine, i, 1880.

[2] Freund: Archiv für klinische Medicine.

an effort. The movement of eyeballs in every direction is unimpaired. Closure of the eyes is accompanied with less force on the right side than on the left. The lower half of the face is relaxed, the corners of the mouth drawn downward, but the action of all the muscles in this region is normal. The tongue is protruded in a straight line, is not atrophic and can be freely moved in all directions. Pupils are equal in size, and react well both to light and upon convergence. The voice has a nasal intonation. The soft palate is raised only slightly on phonation and very imperfectly. At present patient can swallow fluids without having them regurgitate through the nose—it is peculiar, however, that with every swallow he is forced to make two acts of deglutition. Solid food passes down very slowly; patient is forced to drink a great quantity of water, but it neither passes forward through the nose nor does it cause any coughing.

According to the report of the University Poliklinik for throat affections, the abduction of the vocal cords, especially of the left, is limited. The free edge of the left vocal cord, during phonation, shows a slight curve. A laryngoscopic examination made since then revealed no gross disturbance. Acuteness of hearing is markedly diminished. The membrana tympani are slightly retracted and somewhat thickened. The trapezii on both sides are of equal and normal power. There is not atrophy of the muscles of the upper extremities. The active movements are retained and the gross motoric power is not diminished. No rigidity of the muscles of the lower extremity. Tendon reflexes are not lightened. Active movements are retained. The gait presents nothing abnormal. Romberg's sign is absent.

Examination of Eye (Professor Uhthoff).—Bilateral ptosis, almost complete on right side. The movements of the globes are somewhat limited by a well marked paresis of the right rectus internus and of the left rectus superior.

June 1, 1889.—Patient now lays especial stress upon weakness of the masseter muscles; he becomes so tired after taking two bites that he is unable to continue eating.

June 18, 1889.—Patient states that he can chew better from day to day and also that he can see better, because his upper lids do not hang down so low.

June 28, 1889.—Patient states to day that he can swallow better. He is not able to whistle, but thinks it is due to the fact that he has not sufficient power of expiration. Soft palate is elevated only to a very slight degree on phonation.

September 12, 1889.—The ptosis on the right side has disappeared to such an extent as to leave the entire pupils uncovered. Ptosis on the left side is only median as to degree. During movements of the eyeballs upwardly the left one remains behind. The movements in all other directions are normal.

There is still a well-marked weakness of the orbicularis palpebrarum, while the action of the muscles of the lips is normal. The inability to whistle is not due to a weakness of the lips.

The voice is still markedly nasal and the words are not sharply articulated; however, improvement in this respect has also taken place. Examination of the electrical reaction:

Faradic current. { Nerv. facialis sinistra, 120 mm. R.A.
Nerv. facialis dextra, 120 mm. R.A.

Lively contraction of all the branches. Prompt reaction of the soft palate to the faradic current.

Galvanic current. { Nerv. facialis sinistra 20 El. 2 M.A.
Nerv. facialis dextra, 20 El. 2 M. A.

Reaction prompt, no reaction of degeneration. On the whole the electrical examination reveals nothing pathological.

Laryngoscopic Examination.—Vocal cords are of normal color, show no traces of catarrhal inflammation. During phonation a well marked space remains between the vocal cords, the adduction of the left one especially is imperfect. Furthermore there is a well marked paralysis of the crico arytenoideus posteriores, the rima glottidis, instead of enlarging during a deep inspiration, becomes smaller.

Second reception in the hospital, May 8, 1890.

Status.—Patient was discharged in October, 1889, much improved, but was admitted to day, his condition having become much worse. He cannot swallow, speak, or masticate well, the deterioration of his symptoms having occurred very slowly. While drinking, the fluids regurgitate through his nose. Speech is decidedly nasal, articulation very imperfect; S F J are pronounced very imperfectly, instead of B he says MB. The soft palate is not elevated at all during phonation. The reflexes of the pharynx are absent. The tongue is protruded in a straight line, is heavily coated, but neither inspection nor palpation reveal any evidence of atrophy. While patient is speaking, and also on other occasions, a loud stridor is heard during inspiration. He is unable to whistle, although the movements of the lips are perfect. The movements of the tongue in all directions are normal. The muscles of mastication are so weak that the lower jaw can be pressed downward with ease. Slight ptosis on the left side. Normal movements of the eyeballs. Therapy: Iodide of potash, galvanization of the medulla oblongata, faradization of the soft palate.

May 9, 1890.—Patient complains of weakness of the arms. Condition of general nutrition is very imperfect, the subcutaneous fat has disappeared to a great extent. The active movements of the upper extremities are retained, but the muscular force developed is below the normal; the abduction of the arm and the extension of the forearm are especially weak.

There is a well-marked paralysis of the posterior cricoarytenoid muscles; during inspiration the vocal cords do not separate, but, on the contrary, approach each other more closely. Deafness exists to the same degree as formerly. No atrophy of the small muscles of the hand. Movements of the head are retained in all directions and are executed with usual strength.

Ophthalmoscopic Examination (Professor Uhthoff).—Examination of the retina is negative. Slight bilateral ptosis, more marked on the left side than on the right. Reaction of the pupils normal, movements of the eyeballs in all directions perfect. At present fluids are swallowed without regurgitation through the nose. Deglutition is slow, difficult, and accompanied by numerous acts of deglutition. Softened bread is masticated very slowly, and then swallowed without much effort. Passive movements of the lower extremities meet with no resistance, the tendon reflexes are normal, and so are also the active movements. The pulse rate is slightly increased, 104 per minute.

May 13, 1890.—Dysphagia is now complete and patient is also unable to masticate any food. Temperature is increased, 38.4° C. at night. No dulness on percussion is to be found over any portion of the lungs. A few consonant râles are heard above the clavicles.

May 14, 1890.—Patient has grown worse from hour to hour. Had to be fed with the stomach-tube. Lips are cyanotic, pulse is small and rapid; patient is seized with attacks of great anxiety. Temperature, morning, 39.1° C.; evening, 38.1° C. During the night from 13th to 14th, exitus lethalis.

Post-mortem Examination.—Some clotted blood in the longitudinal sinus. The inner surface of the dura mater is dry and glistening. The pia mater over both hemispheres is neither infiltrated nor œdematous, and can easily be separated from the surface of the brain, without showing any adhesions at any place. The ventricles are rather large, but show no pathological contents. The brain substance is anæmic but contains no softened nor sclerotic patches. The region of the corpora quadrigemina is of normal color, shape, and consistence. The

nasal ganglia with the medulla oblongata are removed *in toto* for the purpose of hardening (Miller's fluid). Macroscopically, the spinal cord presents a normal appearance. A few small tubercles are found on the surface of the left pleura. The lungs are hyperæmic, the cut surface somewhat granular, but no other evidence of bronchopneumonia or tuberculosis is to be found. After the lung had been taken out, however, a large tumor, about the size of a duck's egg, was found in the region of the large bronchi, firmly adherent to its surroundings, with caseous hemorrhagic contents (tuberculous gland). The muscles, as far as they are exposed, are normal in color, with the exception of the soft palate, which is somewhat pale.

Microscopic Examination.—The cord was examined in all regions. A serial section was made of medulla, bridge, the region of the corpora quadrigemina, and of the nasal ganglia, and over six hundred sections were mounted. The ascending frontal and parietal convolutions, the peripheric nerves, and the tongue and soft palate were also carefully examined.

1. Cauda equina and filum terminale. All bundles of nerves which were cut in a section through the cauda equina are normal, showing no traces of degeneration.

2. Lumbar region. The entire lumbar region of the cord is remarkable for the wealth of ganglionic cells and nerve-fibres within the gray matter. The ganglionic cells are of usual size, the nucleus and nucleolus well preserved, the prolongations are long, and the protoplasm contains no pigment. The white substance of the lateral and posterior columns does not show the slightest tendency toward sclerosis. The penetrating anterior and posterior roots are intact, the anterior roots, on transverse sections, present nothing abnormal, the individual fibres and the axis-cylinder are of normal size and the interstitial connective tissue is not increased.

3. The dorsal and cervical regions of the cord, the crossing of the pyramidal tracts, and the upper sensorial crossing are in every respect normal; no atrophy of the ganglionic cells, no degeneration of the anterior roots, no sclerosis of the pyramidal tracts.

The hyperglossal centre, in its entire length, shows an unusual number of cells with well preserved prolongations and a fine network of fibres. No changes can be found in the vagus, accessorius, glosso-pharyngeus column. The acusticus centre, both its external and internal sections, is sharply defined and perfectly normal. The centres for the facial and motoric trigeminus are absolutely healthy. The roots issuing from these centres, as well as the pyramidal tract in the region of the bridge and medulla oblongata are not degenerated.

Oculo-motor centre. The nucleus ventralis posterior, the nucleus dorsalis posterior, and the Westphal-Eddinger nucleus are normal. A fresh hemorrhage has partially destroyed the nucleus centralis and lateralis on one side, while those of the other are intact. But the red blood-corpuscles are absolutely unchanged, the tears in the tissues are fresh, and the margins of the destroyed tissue show no evidence of reaction, all of which point to the fact that hemorrhage occurred either during the death agony or at most a short time before death. Three other hemorrhages of the same character were found—one in the vagus centre one in the Westphal-Eddinger nucleus of the right side, and the third in the region of the corpora quadrigemina, just beneath the tegmentum, destroying the raphé. The nasal ganglia were cut into serial sections, neither the internal capsule, nucleus lentiformis, nor thalamus opticus showed either softening or sclerosis. The psycho-motor area of the cortex of the brain was subjected to a careful examination. The sections are thin, the stains with carmin nigrosin and according to the methods of Weigert and Pal are perfect, and, as far as we are able to judge, the tissues present nothing pathological.

In order to show that this case is not an anomaly or an abnormal case of bulbar paralysis, but that it represents a distinct clinical picture, hitherto undescribed as such, I will introduce in a concise form three cases which are in every respect similar to the above case, but were published as clinical and pathological curiosities. The first case of this kind was published by Wilks.[1]

"A robust girl, of healthy appearance, was admitted to the hospital on account of general weakness, she was scarcely able to stand or to move about. She spoke very slowly and had a slight strabismus. The diagnosis of hysteria was made. She remained in this condition about a month; her condition neither became better nor worse. She could scarcely move about; her speech and movements were so slow and measured that they made the impression more of a general lethargy than of any special paralysis. At the end of this period all the symptoms became exaggerated, and in a few days the picture of a bulbar paralysis was complete. Speech was very inarticulate, patient could swallow only with the greatest difficulty, and was unable to cough. The limbs were not paralyzed, patient was able to leave her bed and walk about. after some time dyspnœa set in, which rapidly increased and patient died within a few days. The medulla oblongata was carefully examined, both microscopically and macroscopically and no pathological changes could be found."

This clinical history is somewhat incomplete, but we see that the disease began with general weakness, paresis of one or more of the external muscles of the eye, and disturbance of speech, at first took a chronic course, then underwent an acute exacerbation, dysphagia, and dyspnœa setting in, and patient finally dying of paralysis of respiration. The pathological examination yielded a negative result.

The second case in chronological order is the one published by Oppenheim.[2] "Pauline Jabuke, aged twenty-nine, servant girl, was admitted to the nervous department of the Royal Charité on February 21, 1886. Patient states that she comes from a healthy family and has never been sick, until nine months ago, when she noticed a weakness of the hands, which slowly increased, and then attacked the lower extremities. Four weeks ago she noticed that her lips were becoming weak, that she could not retain food in her mouth very well. A few days later difficulty of deglutition set in, with regurgitation of fluids through the nose. All these disturbances gradually increased in intensity. Patient does not complain of any anomalies of sensation, or of pain and trouble during micturition.

Physical Examination.—Intelligence intact, no psychic disturbances. Pupils are equal, median size, and react to light very promptly. Ophthalmoscopic examination negative (Professor Uhthoff). Nothing abnormal about the conformation of the cranium. Slight, but undoubted paresis of both the superior and inferior branches of the facial. Speech has a nasal intonation, but is otherwise normal. The movements of the lips are not absent, but are very defective. The muscles of mastication are very weak, closure of the jaws is accompanied by very little force. The soft palate is elevated only very slightly during phonation. There is no atrophy of any of the muscles involved, no change of the electrical reaction. No disturbance of sensation. Pulse normal; respiration shallow and superficial. Patient complains of dyspnœa and difficulty in coughing. The active and passive movements of the head and upper and lower extremities are normal. The muscles show no atrophy or change in the electrical reaction, but there is a well-marked weakness or paresis which affects all groups of muscles equally and becomes manifest at every voluntary exertion. The tendon reflexes are normal; no disturbance of sensation. A careful electrical examination failed to reveal the slightest indication of a reaction of degeneration.

The case took a very chronic course, at times some of the symptoms improved, but, on the whole, patient went from bad to worse, the general paresis gradually increased.

[1] Guy's Hospital Reports, 1870. [2] Virchow's Archives, 1887.

the tongue and muscles of mastication became entirely paralyzed, irregular rises of temperature occurred, occasionally without any obvious cause, disturbance of circulation and respiration set in, and patient died, after having been under continual observation for nearly two years.

The post-mortem revealed nothing abnormal, except a "Schluckpneumonie." The medulla oblongata, pons, and the region of the corpora quadrigemina were cut into serial sections and carefully examined, but no evidence of degeneration was found either in the gray nuclei of the floor of the fourth ventricle or in the intramedullary fibre. The peripheric nerves, both cranial and those of the extremities, were examined, and no changes were found. In a word, the anatomical examination was negative.

The third case is the one published by C. Eisenlohr [1] and is remarkable for the remissions which occurred, and for the rapidity with which the symptoms changed even during the course of a single day.

"A Case of Ophthalmoplegia Externa, and Final Bulbar Paralysis, without an Anatomical Basis."—The patient was a girl eighteen years of age, in whom no traces of a hereditary or acquired syphilis could be found. She suffered from childhood with migraine, but whether or not the following symptoms occurred at first with such an attack could not be ascertained. Two years ago patient was suddenly attacked with diplopia and bilateral ptosis, which symptoms disappeared, however, after three weeks (iodide of potash). A year later these same symptoms reappeared, but the intensity and degree of the diplopia was subject to extensive variation. At certain periods of the day patient saw perfectly well, at others double. The ptosis was worse one day on the right side, the next day on the left, at times was absent. She was again treated with iodide of potash, and all symptoms disappeared for a year and a half, when, in connection with an attack of migraine the diplopia and headache returned, and at the same time patient experienced a weakness of both hands. Weakness of the lower extremities, dyspnœa, difficulty of deglutition, disturbance of speech, and weakness of the muscles of mastication followed in short order.

The physical examination revealed an almost complete ophthalmoplegia externa, the movements of the eyeball being almost nil, a bilateral, almost complete ptosis, a marked paresis of the superior and inferior branches of the facial, manifesting itself especially in weakness of the orbicularis palpebrarum and of the muscles of the lips. The tongue is in every respect normal. There is a well marked paresis of the muscles of mastication. The soft palate is elevated only very slightly during phonation, allowing fluids to regurgitate through the nose during the act of deglutition. Acts of respiration are shallow and superficial. The active movements of the head, upper and lower, are retained, but are accompanied by little force, showing well-marked weakness. This weakness is more marked in the extensors of the upper extremity than in the flexors, and more in the small muscles of the hand than in those of the arm or forearm. There is no atrophy of any of the muscles involved. The electrical examination reveals nothing abnormal.

Therapy: Rest in bed, iodide of sodium, mercurial inunctions.

The condition of patient was subject to rapid remissions, but gradually became worse, paralysis of circulation and respiration set in, and patient died two years after the first occurrence of the diplopia.

The post-mortem examination revealed no macroscopic changes in the brain and spinal cord. The microscopic examination showed the cord, medulla oblongata, pons, and peripheric nerves to be normal. Aside from a few fresh hemorrhages and a number of small but otherwise normal fibres in the roots of the facial and hypoglossus nothing pathological was found. In a word, the anatomical examination was negative, although the complex of clinical symptoms was supposed to be characteristic.

In order to avoid the necessity of repeating the clinical symptoms of each case, I have, for the purpose of comparison, drawn up the following table:

	Own Observation.	Case of Wilks.	Case of Oppenheim.	Case of Eisenlohr.
Beginning	Bilateral ptosis; disturbance of deglutition and speech; weakness of muscles of mastication.	Strabismus; weakness of extremities; disturbance of speech.	Disturbance of deglutition; disturbance of speech; weakness of muscles of mastication; weakness of extremities.	Bilateral ptosis; diplopia; weakness of the extremities.
Course and duration	Remissions; chronic; 1½ year.	Duration not given; chronic; acute exacerbation before death.	Remissions; very chronic; 2 years.	Chronic; 1½ year; remissions.
Oculo-motorius	Bilateral ptosis; paresis of two of the recti muscles.	Strabismus (?).	No involvement.	Bilateral ptosis; ophthalmoplegia externa.
Motoric fifth	Great weakness of the muscles of mastication.	Weakness of muscles of mastication.	Paralysis of the muscles of mastication.	Great weakness of the muscles of mastication.
Superior facial	Paresis.	Not mentioned.	Paresis.	Paresis.
Inferior facial	Paresis.	Paresis.	Paresis.	Paresis.
Glosso-pharyngeal	Difficulty of deglutition; paresis of soft palate.	Difficulty of deglutition; paresis of soft palate.	Difficulty of deglutition; paresis of soft palate.	Difficulty of deglutition; paresis of soft palate.
Hypoglossus	Free.	Negative (?).	Slight paresis.	Free.
Vagus	Paresis of vocal cords; disturbance of respiration and circulation.	Disturbance of respiration and circulation.	Paresis of vocal cords; disturbance of circulation and respiration.	Disturbance of circulation and respiration.
Electrical reaction	No degenerative atrophy; no reaction of degeneration.	Negative.	No degenerative atrophy; no reaction of degeneration.	No degenerative atrophy; no reaction of degeneration.
Extremities	Weakness.	Weakness.	Weakness.	Weakness.
Pathological changes	Central and peripheral nervous system normal.	Central and peripheral nervous system normal.	Central and peripheral nervous system normal.	Central and peripheral nervous system normal.
Cause of death	Paralysis of circulation and respiration.	Paralysis of circulation and respiration.	Paralysis of circulation and respiration.	Paralysis of circulation and respiration.

The question arises now, how are we to classify these cases? Do they present a distinct clinical picture which is sharply defined and can be clearly differentiated from the types of diseases described up to date? I believe that we can answer this question in the affirmative.

If we compare the cases, we will find that they agree almost throughout. By this I do not mean to say that every symptom which occurs in the one case recurs in every other, but that they agree in their mode of origin, in their course and termination, in their principal and characteristic symptoms, and that the clinical picture, considered as a whole, differs from the known form of diseases of the central or peripheral nervous system. In the first place, we have a disease of chronic duration. In the case of Wilks the duration is not given; the other cases, however, were under observation from one and a half to two years.

The first symptom is a weakness, a paresis, occurring in some regions supplied by a cranial or spinal nerve, and it seems that the oculo-motor is attacked first with preference, for three of the four cases began with a bilateral ptosis or a paresis of one or more of the other muscles supplied by this nerve. Then there follows, in

[1] Neurologisches Centralblatt, 1887.

slow progression, a disturbance of the function of the facial, both of its superior and inferior branches, of the motoric portion of the fifth, of the glosso-pharyngeal, accessorius and vagus. In but one case was the hypoglossal involved. But the affection is by no means limited to the cranial nerves, but in all cases special stress was laid upon a weakness of the extremities. Without being accompanied at any time with an atrophy of any group of muscles, or with any change of electrical reaction, the paresis gradually increases, in some regions, as, for instance, those supplied by the motoric fifth and the glosso-pharyngeal, to complete paralysis.

The course, as a whole, is chronic and progressive, although in the case of Wilks the development of the bulbar symptoms was completed within a week, and the case of Eisenlohr ended fatally two months after the appearance of dysphagia. Moreover, the cases are notable for the occurrence of well-marked remissions and rapid change of the intensity of some of the symptoms, so that, for instance, in the case of Eisenlohr, the diplopia came and went in the course of a single day, or that the patient was able to swallow well in the morning and at night suffered from dysphagia. However, it is to be observed that these remissions only affected individual symptoms, the disease, as such, taking a progressive course. Death was caused directly by the disease itself, by a paralysis of the circulation and respiration.

The anatomical examination in the four cases yielded a negative result. At least no changes were found in the gray matter of the floor of the fourth ventricle, which could explain the clinical phenomena observed during life. Only in one case (my own) did the examination extend to the cortex of the brain, without revealing, however, any pathological changes. Although the histological technique which is used in working the central nervous system is not of such an exact nature as to enable us to judge with certainty of the finer protoplasmic changes in the cells, I am convinced that, as far as the medulla oblongata is concerned in these cases, we can speak of an absolutely normal condition of this structure, since any pathological changes could have reached their full development, on account of the chronic course of the disease.

In short, we have to deal with a disease which is characterized by a paresis of all the motoric regions of the body, especially those supplied by the cranial nerves, the paresis gradually increasing in some regions to absolute paralysis, without being accompanied by atrophy or by a change of the electrical reaction of the affected muscles, ending fatally in the cases on record, the anatomical examination of the central-nervous system after death yielding a negative result.

The disease can be differentiated from the chronic, progressive, atrophic form of bulbar paralysis (form of Duchenne), *a*, by the absence of atrophy or change in the electrical reaction of the affected groups of muscles; *b*, by the participation in the general paresis of the superior branch of the facial and the oculo-motor, which are never affected in the Duchenne form of bulbar paralysis; *c*, by the rare participation of the hypoglossus, which is affected first in Duchenne's disease; *d*, by the presence of well-marked remissions, and by the rapid variation in the intensity of the symptoms; *e*, by the absence of any pathological changes after death.

It can be differentiated from acute bulbar paralysis and pseudo-bulbar paralysis by the mode of its development, its course and duration, and especially by the absence of any pathological changes after death.

Hysteria can be ruled out without much trouble. We have in these cases a sharply-defined complex of clinical symptoms, which is not to be found in hysteria. Moreover, all symptoms were absent in these cases.

An affection of the peripheric nerves, a peripheral neuritis, is capable of producing bulbar symptoms, as the cases published by Karst, Meyer, and Eisenlohr show. However, in these cases we would expect a degenerative atrophy of the affected muscles and a change in their electrical reaction, both of which signs are absent in our cases. Moreover, the peripheric nerves in these four cases were found to be normal after death, although Eisenlohr found a large number of small but otherwise normal nerve-fibres in the roots of the hypoglossal and facial.

In 1879, Erb,[1] with three cases as a basis, described a complex of symptoms in which he laid especial stress upon ptosis, weakness of the muscles of mastication, and weakness of the muscles of the neck, looking upon a paresis of the superior branch of the facial paresis of the tongue and extremities, and difficulty of deglutition, as being of secondary importance. A superficial comparison would lead one to the conclusion that the disease described in this paper and that described by Erb are identical. But a careful examination of the cases of Erb will show that the two affections differ in those points on which I lay most stress, namely, the presence or absence of degenerative atrophy and change in the electrical reaction; for two of the cases of Erb (the third was examined but once, and then disappeared from view) show a well marked atrophy and a corresponding change of the electrical reaction of the muscles of the tongue, neck, and of the masseters. A post-mortem examination was made in none of the cases, and the supposition which Erb makes in his article that his disease is a nuclear atrophy, a combination of poliencephalitis chronica, superior and inferior, has probably been verified by similar cases which have been published in the last few years.

If, as we have shown, these cases agree with one another, and we are unable to classify them with any of the above forms of nervous diseases, they must form a special class, and to this conclusion I have come.

The etiology of the disease is still a matter of conjecture. That it is a neurosis, as Oppenheim,[2] in speaking of his case, suggests, I doubt. However, the difference of opinion depends only upon the use of a term. Oppenheim thinks that it may be a neurosis, a functional affection, because he was unable to find any anatomical basis for the symptoms. He is not, however, of the opinion that one will never be found. The possibility that the affection may be due to a chronic intoxication, a ptomaïne or toxic-albumin poisoning, cannot be denied. We know of chemical poisons which affect only the motor apparatus of the body, and leave the sensory tracts intact. In the same manner we can imagine that a toxic agent, having its origin in the body, might act in such a manner upon the cortical centres of the brain, or on the peripheric nerves, as to bring about a complex of symptoms whose main characteristic is a slowly progressing paresis. In my case, we might look upon the large caseous tubercular bronchial gland as such a source of intoxication; in the other three cases, however, such sources are absent.

Finally, I would like to call attention to the possibility that the cause of the disease may be a pathological change in the cortex of the brain which has escaped our attention. The pathology of the cortex of the brain is still in its infancy, and the histological methods which we can make use of in the preparation of tissues hardened in Müller's fluid are not sufficiently exact to enable us to judge with certainty whether or not minute changes have taken place in the protoplasm of the ganglionic cells and their prolongation. In order to clear up this point we will have to make use of, in future cases, the more improved technique of modern histology, especially of methods of rapid fixation of the tissues, and of embedding in paraffin, which will permit us to make thinner section.

It is Chronicled in French journals as a fact of no little significance that the candidacy of a certain Mlle. Roussel has been favorably reported upon by a committee of the Rouen Medical Society. The old world is moving.

THE CYLINDRICAL VAGINAL PESSARY-TAMPON *VERSUS* OTHER PESSARIES—INDICATIONS AND CONTRAINDICATIONS TO ITS USES.[1]

By JAMES STAFFORD, M.D.,

ATTENDING GYNECOLOGIST TO THE NORTHERN DISPENSARY; ASSISTANT ATTENDING GYNECOLOGIST TO BELLEVUE HOSPITAL, OUT-PATIENT DEPARTMENT; CLINICAL ASSISTANT IN GYNECOLOGY AND SURGERY AT THE NEW YORK POLYCLINIC; MEMBER OF THE SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL, ETC.

From the early history of gynecology various supportive measures have been employed in the treatment of displacements of the uterus, Fallopian tubes, and ovaries; but in every instance where symptoms occurred there was found some coexisting pathological condition to which these symptoms might be referred as an etiological factor. Thus it has become a matter of opinion as to whether we should treat the displacement *per se*, the coexisting conditions, or both the displacement and the morphological conditions. Some gynecologists argue that the symptoms attending displacements, save in those cases due to neoplasms or perimetritis, are due chiefly to the malposition, that the concomitant conditions are merely complications and will be of little account when the faulty position shall have been rectified; while others believe that displacements are at first a production of, and later a complication of, the pre-existing disease, and that the chief desideratum is the bringing about of a physiological condition in the parts, and when this condition shall have been attained supports will be unnecessary, as the abnormality of position will either have rectified itself, or, if it still exist, will give rise to no untoward symptoms. Those holding to the first belief rely with implicit confidence upon the pessary and douches, and think if they fail to obtain satisfactory results it must be due to an error in selection of the instrument, to its improper adaptation, or that it has itself become displaced; and they are constantly bearing these things in mind to account for bad results. Those physicians holding to the more recent view place their main reliance not only upon support, but, in addition, local medication. This combined treatment is found in the cylindrical pessary-tampon.

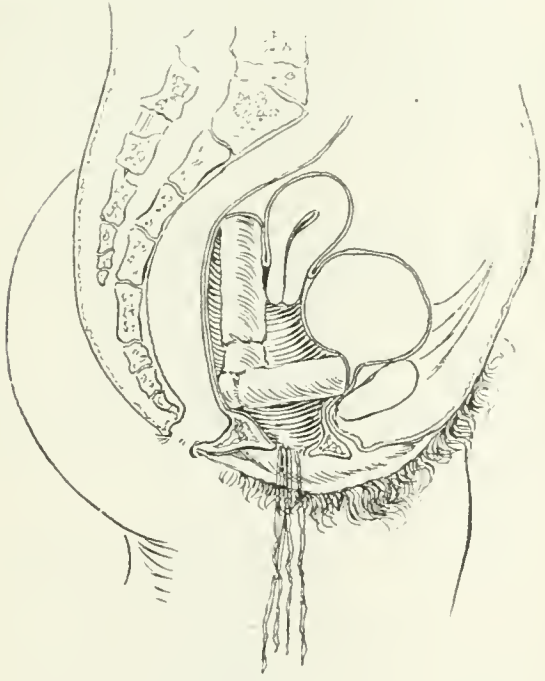

Fig. 1.

In the construction of pessaries many of the metals, wood, glass, ebonite, and rubber have been used, but of the various materials rubber seems to have the largest number of desired qualities, viz., smoothness, lightness, elasticity, resistance to action of vaginal secretions, and the ease with which it can be moulded to meet the requirements of each individual case. Uterine supports of such varied shapes have been employed that as many a gynecologist has devised a pessary to which his appellation has been attached as has the obstetrician his forceps, or the surgeon his artery-clamps; so that the variety of pessaries is legion. Although the pessary to a certain extent restores the displaced parts, thus relieving symptoms, diminishing pelvic congestion and the tendency to cystocele and rectocele, yet this effect is largely mechanical, there being but little curative action, as may be proven in many cases by return of the symptoms, and displacement when the treatment is discontinued for a time. Then, again, the benefits derived are to a great extent counterbalanced by the harmful effects of the pessaries, and not the least of these dangers, but the most formidable of them all, is probably perimetritis. During the past few years, since the pelvic cavity is explored with a great degree of safety, many of these cases have been saved from chronic invalidism or death. The untoward effects are chiefly due to two causes, viz., pressure and lack of cleanliness. From these causes a septic process is developed which may result in vesico-vaginal or recto-vaginal fistulæ, erosion of the cervix, septic endometritis, or may be of sufficient virulence to invade the appendages disastrously. It may be justly claimed that these results are not common to obtain in subjects wearing a pessary, but it can just as correctly be claimed that septic causes exist in each instance, that in every woman who wears this instrument there is a solution of continuity at the point of pressure varying in degree, and which may result as before stated, and that so long as it is worn the patient is in constant danger of such development. The care of the toilet of these parts, the use of antiseptic douches, etc., of course lessen the dangers, but unfortunately the majority of women wearing pessaries are among the worthy tenement class, those to whom general cleanliness is often a stranger; hence the care of these parts, although kept cleanly at first, is often neglected. It has been my lot in public practice to see many cases of erosions, both of the vagina and cervix, several cases of endocervicitis, a few cases of fistula arising from the wearing of pessaries, and some cases of perimetritis that were probably due to the same cause; but from the constant use of the pessary-tampon, extending over a period of four or five years, I have not seen over two erosions, and never an abrasion, in those cases where but one tampon was used. One extreme case of fistula I recall in which a pessary had been worn without removal for nine consecutive years, there resulting an opening into the bladder of sufficient calibre to admit the tip of the finger.

I claim for the cylindrical pessary-tampon all of the advantages found in a pessary, and in addition to its being fully as effective as a support, there is its medicinal action, which is a matter of great importance; and lastly, that it is a safe contrasted with a dangerous appliance. Perfection in construction, size, material used, and proper adaptation of the pessary-tampon to each individual case, is fully as important as in the use of pessaries. Lamb's wool, borated, plain absorbent, and other medicated cottons, have been used in the manufacture of pessary-tampons, but I prefer borated cotton prepared in thin layers, as it is antiseptic and can be readily made into the desired shape and density. Assorted sizes and lengths should be at hand, ranging from one and three-quarters to three inches in length, and from three-quarters to one and one-half inch in diameter. To make the pessary-tampon correctly is an important thing, as it is as much in the faulty manufacture as in other details of treatment that they are not in more general use to day. The sections of cotton cut should vary from six to eighteen inches in length, according to the thickness of the cotton, and from one and three-quarters to three inches in width, varying with the length of the pessary-tampon desired. The prepared strip should be placed upon a clean, hard

[1] Read before the Society of the Alumni of Bellevue Hospital, March 2, 1892.

surface, and the roll begun as in a bandage; then the thumbs and first two fingers of both hands are used to continue the roll and to make pressure, while the third fingers are employed to make the ends true and firm. A moderate amount of force is required in construction, but it is not desired to make the mass entirely resisting. When support is the chief desideratum the cylinder should have the same density throughout; and at the ends this is especially important, as if not correctly formed at these parts its pessary action will be greatly impaired. When medication is chiefly desired, or a certain degree of hyperæsthesia obtains in the perimetrium, the end first inserted may be left somewhat soft, thus holding more of the medicament and affording all the support the patient can safely tolerate. The last turn of the cotton having been made smooth, a piece of strong twine, about eighteen inches in length, is wrapped twice about it and so tied that the ends of the twine are left of equal length. This cord serves not only to keep the pessary-tampon in shape, but also to aid the patient in its removal. For the medication of pessary tampons solutions of various drugs in glycerine have been employed. Among these the fifty per cent. solution of boro glyceride, in strength of from one to sixteen to one to six or eight holds a prominent place. To this solution may be added, if an astringent effect is desired, pulverized alum one to sixteen, or should the alum prove too irritating, as is sometimes the case, the acetate of aluminum may be used in about the same proportion. Many are the solutions used to medicate pessary-tampons, but, so far as I can distinguish, the above preparations will accomplish all that may be gained by any of the various complex mixtures. The pessary-tampons should be thoroughly saturated in the solution, and to this end it is better that they be left in the liquid for some time before being used. Preparatory to treatment the patient assumes the left semi-prone position, a long-bladed Sims speculum is inserted, the vagina is mopped out with a solution of corrosive sublimate, strength one to three thousand, and dried with a bit of cotton. When but one tampon is used it should always be inserted posterior to the cervix uteri. This is readily done in most positions of the uterus if an assistant holds the speculum, thus leaving a hand with which to hold the depressor; but if alone, I am in the habit of placing one end of the depressor at the postero-cervico-vaginal junction, and letting the other end rest upon the latero-vaginal wall. I make the application by sliding the pessary-tampon between the speculum and depressor into position, then holding it with the dressing-forceps while the speculum and depressor are removed, and then tilt the lower end of it toward the sacrum. The lower end of the pessary-tampon should reach to a point just above the internal sphincter ani, as at this point, where the rectum and anus form an angle, there seems to be a slight projection, which, aided by the backward and downward pressure of the bladder, is a material aid in holding the pessary tampon in position. If too long or too short to reach this point the position will be faulty, and it will either cause pain necessitating its removal or it will fall out. Pessary-tampons in average cases may be safely left *in situ* for from one to four days, but should they cause pain or much discomfort must be removed at once. It is well to advise a patient to this effect at the commencement of a course of treatment, and thus avoid unfavorable results. After removal of the pessary-tampon medicated douches of hot water are used once or twice a day, for one or two days, before a succeeding application is made.

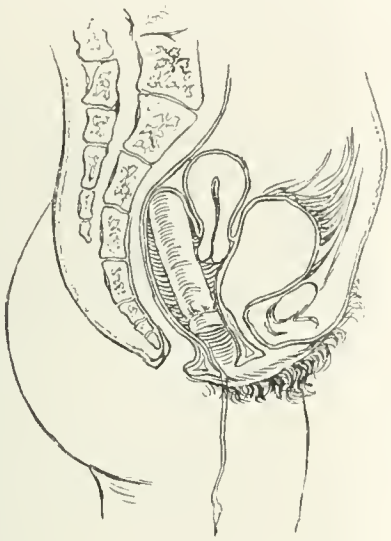

FIG. 2.

Now let us consider some of the abnormal conditions of the pelvic organs in which the pessary-tampon has been used beneficially. Firstly, conditions of the uterus; secondly, of the tubes and ovaries, and lastly, of the bladder and rectum. In cases of uterine subinvolution, following either labor at term or abortion, having as complications catarrhal endometritis, anterior or posterior displacement of the uterus, with perhaps slight laceration of the cervix uteri and symptoms of menorrhagia or metrorrhagia, extreme nervousness, and maybe dysmenorrhœa, pessary-tampons usually act as a specific. A diminution in the size of the uterus may be noted from time to time, and coincident with this that the faulty position is becoming rectified as the muscular wall of the uterus regains its tone, that the endometritis is subsiding, that the laceration is healing, so that in a period of from four to six weeks oftentimes the patient may be discharged cured. By this time menstruation will have occurred at the proper time without dysmenorrhœa. The pessary action favors drainage, while the medicament improves the muscular tone, lessens congestion, and improves the pelvic circulation. I had a case illustrative of the above condition referred me by a physician a few weeks since—a Mrs. L——, who had continued to have irregular menstruation, and at times metrorrhagia, for the past year. There was a history of probable miscarriage at about the second or third week as a cause. The patient told me she had been under medical treatment for this condition since her illness began, and that she had not improved; also that she had been flowing continuously for a period of seven weeks previous to her first office visit. A careful examination revealed a subinvoluted, anteverted uterus, with slight cervical laceration. She was anæmic and extremely nervous. By applications of pessary-tampons twice a week, and douches daily, when the tampons were not in place, the uterus became of normal size, the leucorrhœa subsided, the next menstruation occurred upon the twenty-eighth day, extreme nervousness subsided, likewise her various aches and pains, so that at the end of two months' treatment she was restored to health. In this case I used care to pull down the cervix so as to place the pessary tampon well up behind it, so that as involution should take place and the muscle of the uterus regain its tone it would raise the fundus into normal position. The majority of cases of slight laceration of the cervix, if treatment be commenced early, while the tear is recent, say within the third or fourth week after it occurred, may be entirely cured. In lacerations of longer standing, when a hypertrophic and hyperplastic change has taken place in and about the torn surfaces, the pessary-tampons should be used until a line of demarcation between the healthy and diseased tissues can be made out, and until the hard, indurated condition of the cervix has softened and become more of a normal color and feel; then is the time to do a trachelorrhaphy or amputation of the cervix. The same treatment should obtain in glandular disease of the cervix, and if carefully carried out there is no excuse for an imperfect result, provided all of the diseased tissue is removed at the operation. In nulliparæ, when dysmenorrhœa has occurred for a long time, and at last becomes so severe that the patient consents to an examination, and upon examination you find the uterus enlarged and the endometrium the subject of catarrhal inflammation, many physicians would dilate the cervix and make applications to the endometrium; but in a large per centage of cases I have found the pessary-tampon alone to accomplish a perfect cure. The pessary action tends to rectify any abnormal position, and the osmotic action

of the medicament diminishes the swollen condition of the endometrium, thus enlarging the internal os and doing in a different way what is done by the dilators, and the results seem to me to be more permanent. At the menopanse, in cases where the endometrium is hyperæsthetic and the patient suffering much from reflex symptoms, the pessary-tampons will often anhihilate these unpleasant symptoms. I would suggest the same treatment in the excessive vomiting of pregnancy, thinking it might in certain instances relieve this reflex symptom In retroversion of the uterus, with adhesions, when the appendages are apparently normal, by using graded sizes of pessary tampons, in a large per centage of cases the adhesions may be induced to separate and the patient made comparatively well. In the infantile and so-called superinvoluted uterus pessary-tampons benefit by developing the uterus, thus relieving the dysmenorrhœa and many times the functional sterility. Prolapsus uteri is treated successfully by the same method, save that the applications are made somewhat differently. Two pessary-tampons are used. The first should fit moderately close, and when well inserted reach to within half an inch of the junction of the rectum and anus. The second pessary-tampon should be inserted transversely to the first, the proximal end being placed against the upper urethra and bladder, while the distal end is slipped along the grove of the speculum, abutting against the first pessary-tampon and reaching to a point just above the internal sphincter ani. The crossed tampon should be of fairly good size, and of sufficient length to make a moderate amount of pressure on the ends. As the patient assumes the erect posture the weight of the uterus is supported mainly by the distal position of the transverse pessary-tampon. The anterior end of the transverse pessary-tampon is supported mainly by the pubic bone, while the distal end is held in place by the same structures that hold in the single pessary-tampon. This treatment is also very beneficial in utero-gestation complicated by retroversion, or prolapse of the uterus, by holding the fundus of the uterus away from the promontory of the sacrum until development has caused the uterus to rise out of the pelvis. A frequent cause of miscarriage is thus often avoided. In cases of congested and enlarged ovaries attended by prolapse the single pessary-tampons benefit. In these cases, where the enlarged ovary is posterior to the uterus, it will relieve the symptoms like magic. Subacute and chronic catarrhal salpingitis is improved by an occasional resort to this treatment, and many cases, especially among the upper classes, who are not required to toil for their daily sustenance, go on for years escaping operation and feeling comparatively well. Cases of subacute and chronic cystitis are improved, and especially those cases due to the decomposition of residual urine in cystocele; first employing the single pessary-tampon, using care to avoid traumatism in the introduction, and as the treatment is tolerated using the crossed tampons. The bladder will thus be supported and be effectually drained at each micturition, and be relieved from any pressure or dragging of the uterus. This treatment is especially beneficial in the early months of pregnancy in multiparæ who are annoyed by frequent micturition or incontinence of urine. The single rectal condition I wish to mention is rectocele. Here the action is not unlike the truss in hernia, merely by pressure.

The contra-indications to the use of the pessary-tampon are acute pelvic inflammation, pelvic abscess during menstruation, and, in short, in any cases where there is danger of obstructing uterine drainage, or by traumatism of instruments or pessary tampons, of increasing a perimetritis. A distended rectum, acute cystitis, and acute vaginitis should be included under the same heading.

In conclusion, I wish to make a few comparisons between the pessary-tampon and the pessary. In the first place, as to the shape. With the pessary-tampon you have the simple, single cylinder, and have to judge merely of its size and length, while with the pessary you have a variety of complex shapes and sizes from which to make your selection, but even then the instrument often has to be remodelled to meet the requirements of the case. As the pessary is not antiseptic, and the pressure is often borne by a narrow rim, there is always danger from ulceration and sepsis, while with the pessary-tampon, which is antiseptic, the superincumbent weight is distributed over a larger area, and hence erosions, perimetritis, and fistulæ are not expected from its use. To derive benefit from a pessary it has to be worn for years, as it has so little curative action, while with the pessary-tampon a large per centage of cases are made well after a few weeks' treatment. As is well known, patients wearing a pessary are often negligent about returning for examination; they feel better and often do not present themselves for treatment until the damage is done, as occurred in the fistula case before mentioned. With the pessary tampon the treatment is more exacting. Instructions are given to remove it at a given time, then to use certain douches, and to return for treatment upon a given day. With the pessary treatment patients are often told to remove the pessary to cleanse it, to take a douche, and to reinsert the pessary themselves, and to call for office treatment should they suffer much pain or have much discharge. The introduction of the pessary by the patient, of course, may or may not be faulty. With the pessary-tampons the applications are always made by the physician, and never by the patient, and as the return office visits are more regular and frequent it enables a closer observation of the case. Even should a patient wearing a pessary-tampon fail to return for treatment, there is but little danger of her neglecting to remove it, especially if she be married, as her conservative husband, who cares for the many family necessities would undoubtedly assist the patient in remembering the time for its removal, if not taking the responsibility himself of advising it. If unmarried, the unpleasant sensation from the watery flow and the string will serve as a reminder, so that the application will not be left in too long. In the use of a pessary to support a prolapsed ovary cases occur in which the ovary or tube has been injured by being caught behind the instrument. Such cases never occur in the use of the pessary-tampon. The simpler the instrument is in construction the more useful and safer it is. This general principle applies with peculiar force to the pessaries described, and the practitioner will not be surprised to find that this simple medicated roll of cotton holds a wider range of usefulness than the whole armamentarium of pessaries.

For the illustrations I am indebted to my friend Mr. Bert Wilder, an artist for *Harper's Weekly*.

A Lizard in a Woman's Stomach.—A new version of a good old country tale is to hand from Cornwall. A woman, named Jane Rowe, residing at Marazion, had, we are told, for several years suffered from violent pains in the stomach, from which she was unable to obtain any relief, although continually under medical treatment. On a recent occasion, after taking some medicine, she had a severe attack of vomiting, in the course of which she threw up a living lizard, from four to five inches in length. Dr. J. Mudge, who has been the woman's medical attendant, has preserved the lizard, which he believes must have been in her stomach for many years. Since the reptile was ejected Mrs. Rowe has been almost entirely free from pain. All we can say is that if Dr. Mudge believes anything of the kind he ought to be sentenced to three months' hard study of natural history and old story books. We prefer, however, to charitably assume that this statement is merely an attempt to give a fictitious appearance of authenticity.—*Medical Press.*

A Grocer was lately prosecuted at Dijon for practising pharmacy illegally, and had to pay five hundred francs, and to advertise the conviction at his own expense in five of the most popular newspapers in the neighborhood.

PACHYMENINGITIS HÆMORRHAGICA INTERNA CHRONICA.[1]

Report of Case and Review of Pathology.

By FRANK C. HOYT, M.D.,

ASSISTANT PHYSICIAN AND PATHOLOGIST, ASYLUM NO. 2, ST. JOSEPH, MO.

Mr. President and Gentlemen: I invite your attention to the following report of a case, which is, both in its clinical and pathological aspects, of unusual interest. For the clinical history I am indebted to my associate, Dr. C. H. Wallace, whose close observation of the case greatly enhanced its scientific value:

L. W——, male, age at death sixty-three, white, married, farmer, a non-consumer of alcohol, excessive user of tobacco, no history of syphilis, was admitted in August, 1888, with a history of insanity of one year's duration. His mental alienation was first manifested by suicidal inclinations, and a tendency to wander away from home. Physical condition at time of admission was good. The patient ran the usual course of a case of chronic insanity, his mental condition steadily deteriorating until by December, 1890, he was classed as a case of terminal dementia.

January 10th he was observed to be unusually stupid and confused, complained of some headache, and vomited several times. As the patient was addicted to drinking the contents of spittoons, the latter symptom was attributed to that cause. After a brisk purgative this condition was in a measure relieved, but the patient was plainly more stupid and less active than before the attack. Between this date and June he had several similar attacks, which always left him in a worse mental condition. June 28, 1891, he was found, at the rising bell, to be in a condition of somnolence, from which he could be aroused only with great difficulty. He was unable to stand or walk, but when supported used all his limbs fairly well. By evening of the same day he was unable to perform any conscious movement, but would move all of his limbs when they were pricked with a pin. He now had a temperature of 102.5° F., pulse slow and full, pupils slightly contracted and very sluggish, breathing slow and labored, the patient groaning as if in pain. June 29th his condition was aggravated, breathing stertorous, face pale, and lips blue, pupils contracted, temperature 101.5° F.; he tossed about in bed and evacuated his bowels and bladder involuntarily. Coma became profound and he rapidly grew worse, and died July 1, 1891.

Autopsy, twenty hours after death.—Body poorly nourished, rigor mortis marked. No marks of violence were found, after a very careful examination of the head and scalp. The skull was large and symmetrical, and the external periosteum was normal. Calvarium was unusually thin and friable, its inner surface bearing the impression of numerous Pacchionian bodies, but it was of normal color and consistence. The calvarium was removed and detached from the dura mater without difficulty, exposing the external surface of that membrane, which was seen to be free from any evidences of disease. The longitudinal sinus was slit up and found free from thrombi. The dura mater was then incised over the right bregmatic region, where a bulging appearance and a sense of fluctuation pointed to an abnormal condition. The incision liberated about four ounces of dark, partly coagulated blood, leaving a well-defined cavity which had contained the hæmatoma, as the condition proved to be.

In order to observe this formation the dura was carefully removed and the following conditions were noted: The entire internal surface of the dura mater of the convexity, the falx cerebri, the falx and tentorium cerebelli, was lined with a neo-membrane of an average thickness of about one-fifteenth of an inch, and of a reddish-brown color, having the appearance of a recent extravasation of blood. A portion of this membrane was hardened in alcohol, vertical sections made, stained with hæmatoxylon, and mounted in balsam. Upon examination the membrane was found to consist (see Fig. 1) of a fine net-work of fibrils, which contained red blood-corpuscles, blood-coloring matter, and white corpuscles of various sizes

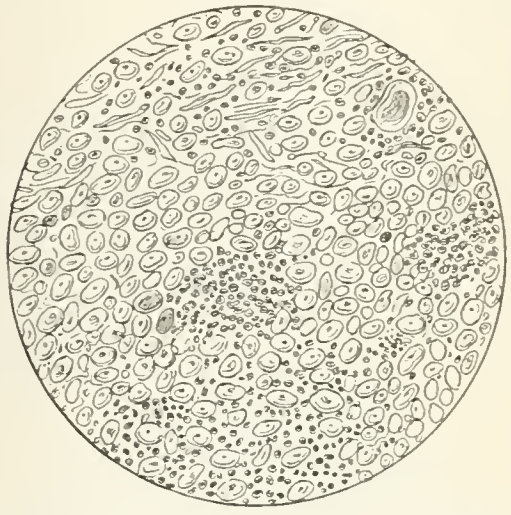

Fig. 1.—Vertical Section of False Membrane Attached to Dura Mater.

and shapes, many having become elongated to form spindle-cells.

The preponderance of leucocytes in various degrees of transformation, and the presence of red blood-corpuscles, in some instances disintegrated, and in others fairly normal in appearance, justifies the conclusion that this membrane is the result of a comparatively recent hemorrhage. The upper surface, as shown in the drawing, is evidently more highly organized than the lower, as it contains a newly formed vessel, and the spindle-cells can be seen arranging themselves into rows for the formation of connective tissue. This membrane, while attached to the dura mater, could be stripped off, and, with the following exceptions, left the internal surface of the dura intact and free from any evidences of inflammation. The exceptions were several small patches of adhesion between the dura and the false membrane, which carried thin, friable vessels of large calibre. At these points there was undoubtedly organic union between the two membranes. At all other portions of the dural surface, save at the site of the hæmatoma, was a second neo-membrane, much thinner than the first described, whitish in

Fig. 2.—False Membrane Attached to Pia Mater, and Forming the Limiting Membrane to the Hæmatoma.

appearance, reasonably dense in structure, and attached loosely to the pia arachnoid below and the reddish-brown membrane above. The thinnest part of this membrane was prepared for the microscope without cutting, and presented the appearance illustrated by Fig. 2. It will

[1] Read before the Mississippi Valley Medical Association, St. Louis, Mo., October 15, 1891.

be seen that this membrane has advanced to a higher stage of organization than the first examined. It is seen to carry a number of large blood vessels, interlacing and anastomosing freely, and very irregular in size, shape, and direction. Several large vessels are seen with thicker walls, in which some fibrous tissue can be made out. These vessels evidently pass from the membrane to the dura above and the pia arachnoid below. The transformation of leucocytes has progressed, and cells of various sizes can be seen arranging themselves into chains and groups, forming a net work of a new connective tissue. The red blood corpuscles have disappeared, leaving here and there small deposits of blood-coloring matter.

The structure proves undoubtedly that this thin membrane, lying next to the pia arachnoid, was formed from the first extravasation of blood, which probably occurred as early as January, the date of the first attack of somnolence; it became organized, new vessels were formed, and another extravasation took place in June, which resulted in the partially organized membrane shown in Fig. 1. The fatal hæmatoma was without doubt derived from some of the new vessels which passed from the pia to the dura, supplying both false membranes.

At the points of adhesion between the dura mater and the first neo-membrane, the vessels passing from the dura

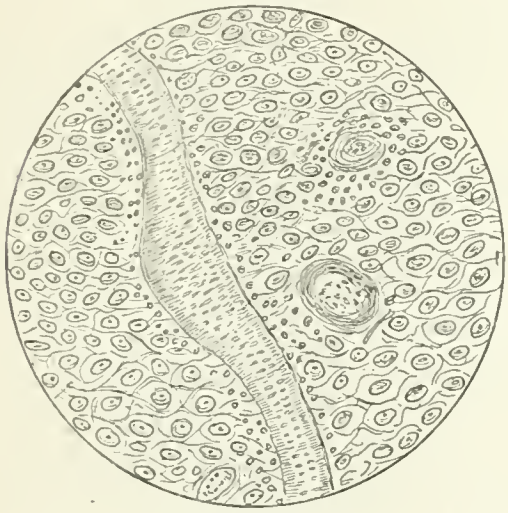

Fig. 3.—Vertical Section of Pia Mater, showing Dilated Vessel.

through the false membrane were traced into the second membrane and into the pia mater. A transverse section of one of these vessels showed it to be arterial in size, but capillary in structure. Its walls consisted mainly of the intima, with a very thin layer of imperfectly formed fibrous tissue.

At the site of the hæmatoma in the subdural space, in the right parietal region, the cavity into which the blood had been poured was found to have been formed between the first and second false membranes, the lower, thinner one forming the limiting membrane for the blood tumor. The cavity was about five inches long, three wide, and covered the frontal and parietal lobes.

The pia mater was next examined and found to be injected, thickened, and opaque, its vessels dilated and tortuous. At the anterior portion of the right frontal lobe the pia was deeply infiltrated, and extensive fibrino-purulent deposits were noticed. A section through the thickest portion, stained and mounted, exhibited characteristic changes (see Fig. 3). The cellular infiltration is marked, and considerable fibrous hyperplasia can be observed. The vessels present the most striking changes, their walls being thin and hyaline or infiltrated. All the vessels examined were dilated, pouched, and varicose. The peri-vascular lymph-spaces were crowded with leucocytes, some red corpuscles also being noticed. The brain as a whole was very much atrophied, weighing only thirty-nine ounces, the right hemisphere being perceptibly smaller from the pressure of the hæmatoma. On section the tissue was found to be firmer than normal, the gray matter very thin, the sulci shallow, and the puncta vasculosa prominent and oozing. The velum interpositum was thickened and injected, and the ependyma of the ventricles soft and granular. Further examination revealed nothing of importance. The condition, of which I consider this case a good type, has been described by writers as pachymeningitis interna hæmorrhagica, hæmatoma duræ matris, arachnoid cyst, etc.

As ordinarily treated of in text-books, the affection may be briefly described as follows: It consists in an effusion or extravasation of blood, by diapedesis or actual rupture of a vessel, into the subdural space. This blood, when the hemorrhage is not too rapid, becomes organized into a pseudo membrane, new vessels form, and their imperfect structure renders them prone to rupture, and leads to repeated hemorrhages and the formation of other false membranes. This process may be continued indefinitely, until as many as twenty false membranes are formed, the case terminating finally in death from a sudden and large hemorrhage. It has a decided preference for the male sex, and is also a disease of advanced life, the few cases reported as occurring in early life being due to traumatism or some grave general disease. It is found most often with psychoses of a chronic type, especially in general paresis, and alcoholic and senile dementia.

Remarkable as it may seem, yet this condition, so simple in its anatomical character, and so accessible to study, is the subject of great controversy as regards its pathology. Throwing aside all consideration of cases known to be due to traumatism, or to focal disease, we will turn our attention to those subdural hemorrhages associated generally with the formation of false membranes.

Houssard, a representative of the older school, held that the condition was primarily hemorrhagic, and that the new membranes were formed substantially of the fibrin of the extravasated blood. Kremiansky thought the hemorrhage was due to rupture of the middle meningeal artery, but this position was proven to be untenable, as a rupture of that vessel would form a hæmatoma between the dura mater and the bone. The views of Houssard met with general acceptance until Virchow published his investigations, in 1856, and in a measure caused a revolution of thought on the subject. His explanation was to the effect that there was a primary inflammation of the dura mater, which resulted in the formation of a thin vascular membrane, from which were derived the successive hemorrhages and the false membranes.

The majority of writers followed the teaching of Virchow thereafter, but a few dissented from his teaching, notably Sperling and Huguenin.[1] The latter, in an excellent article, takes the stand that the condition is primarily hemorrhagic and not inflammatory, thus returning to the old doctrine. He believes that the primary hemorrhage takes place from the veins which pass from the convexity of the brain to the longitudinal sinus, and possibly from the vessel of the Pacchionian bodies. He attaches great weight to the changes which take place in the blood-vessels and predispose them to rupture. Also that the brain atrophy renders rupture more probable. Of the most recent writers Clouston[2] describes the condition, saying, "This is the so-called pachymeningitis hæmorrhagica interna of the Germans, a ridiculous and misleading name, for it is not the result of inflammation at all. . . . It implies a very great intensity of morbid action in the convolutions, and probably also great and sudden changes in the blood-pressure within the cranium." Ross[3] gives the views of both Virchow and Huguenin without committing himself to either side of the question, though he has an evident leaning toward Virchow's theory. H. C. Wood[4] defines it as "a disease in which there is a chronic inflammation of the dura mater, with

[3] Diseases of Nervous System, vol ii., p. 693.
[4] Nervous Diseases and their Diagnosis, p. 406. 1887.

the formation of a bloody growth or tumor, due to, or connected with, repeated hemorrhages into the part." Eichorst [1] also defines the disease as "inflammatory changes of the inner surface of the dura mater," but goes on to describe the various theories, giving preference to that of primary extravasation.

E. C. Seguin [2] says: "The best statement to make about the disease, in our opinion, is that there are two forms of it, one very rare, in which hemorrhage from pia vessels occurs on the clot because organized; and a second, including by far the majority of non-traumatic cases, in which a true pachymeningitis interna occurs, followed by hemorrhage from the vascular channels in the young tissue, fresh inflammatory action, renewed hemorrhages," etc.

Gowers [3] states that the malady is very rare, "and is indeed of interest chiefly as a pathological curiosity and enigma, for it has been seldom even suspected during life," etc. In reference to its pathology, he adds, after giving the views of Virchow and Huguenin: "The question is undecided; provisionally, however, the disease may be kept in its place among the varieties of inflammation."

Delafield and Prudden [4] refer to it as an important form of chronic inflammation of the internal surface of the dura. Ziegler [5] follows Virchow, and describes the affection as a chronic inflammation of the internal surface of the dura mater. After the admirable article of Huguenin, referred to above, the contribution of Joseph Wiglesworth [6] is probably the most important. This writer gives the result of a study of forty-two cases of hæmatoma duræ, and in reference to the pathology concludes that the old theory, *i.e.*, of primary extravasation, is best supported by his experience. He says the condition is the result, not of pachymeningitis, but of an effusion of blood beneath the dura mater. "Such effusions are especially liable to occur in the insane, by reason of the loss of support sustained by the meningeal vessels, on account of the convolutional atrophy which is so marked a concomitant of insanity."

Sufficient authorities have been quoted, I think, to show how widely diverse are the opinions held. The first question which arises is whether the condition be an inflammatory affection of the internal dura mater, followed by a vascular exudate, subsequent hemorrhage, organization and the formation of false membranes; or whether the primary step is a hemorrhage, followed, as above, by organization and repeated hemorrhages.

The theory of Virchow, which presupposes an inflammation of the internal surface of the dura mater, has been, I think, satisfactorily disproven by the investigations of Huguenin, Sperling, Wiglesworth, and others. Sperling showed by experiments on rabbits that the injection of blood under the dura terminated, at the end of two or three weeks, in the formation of new membranes which were exactly like those found in pachymeningitis interna. He also found that the injection of irritants into the subdural space of animals was followed by purulent, but never by hemorrhagic, pachymeningitis. He also found that the injection of defibrinated blood was not followed by the formation of false membranes.

Wiglesworth found in one-sixth of his cases that there was fluid blood and clot in the subdural space, without the presence of any trace of false membranes on the under-surface of the dura. He very rightly concludes that if the hæmatoma can be formed without the presence of a membrane, there can be no necessity of calling in the aid of such a formation to account for the hemorrhages. But the decisive point is the microscopical examination of the internal surface of the dura mater in cases of hæmatoma. If the disease is an inflammation primarily, and if it is the cause of extensive extravasations and formations of layer after layer of neo-membranes, the microscope should show indubitable evidence of such conditions.

But here the advocates of inflammation fail to make a case. Virchow, to be sure, in some cases found slight evidences of inflammation, as well as the presence of a thin vascular membrane attached to the inner surface of the dura mater. But his conclusions were drawn from cases in which the process had advanced sufficiently far for the slight inflammation to be accounted for by the irritation caused by the adjacent extravasation. In addition to this, the inflammation is described by many writers, and our own case is corroborative, as occurring in patches, and at those points where organic union had taken place between the dura mater and the neo-membranes.

At other portions of the dura the internal surface, after

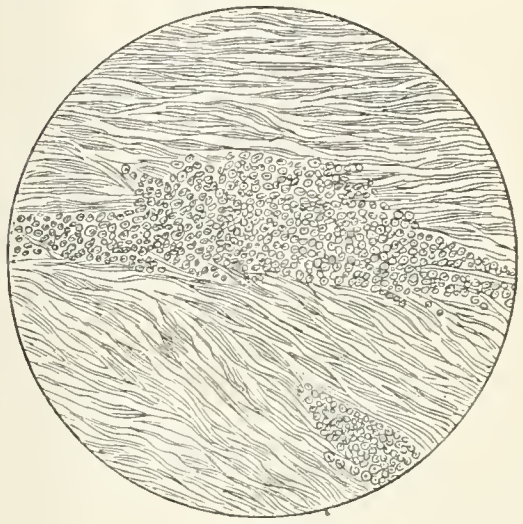

Fig. 4.—Vertical Section of Dura Mater, showing Hemorrhage into its Tissue.

stripping off the false membrane, was white and pearly. Sections of the dura mater made by Wiglesworth showed hemorrhages into its substance, and at the points of adhesion very slight evidences of inflammation, such as small accumulations of leucocytes and abnormally distinct nuclei of the fibrous bundles. In the case which I have just reported I prepared a number of sections of the dura, finding, as illustrated in Fig. 4, little more than hemorrhage into the substance of the membrane, or between its lamellæ. In the report from the State Hospital at Norristown, Pa., Dr. F. X. Dercum, the able pathologist of that institution, gives the result of a series of investigations carried on by him, he also finding hemorrhages into the dura, but no evidences of inflammatory processes.

From the study of the dura mater in a considerable number of cases of general paresis of the insane and chronic insanity, together with a minute examination of the membranes in this case, and upon the authority of Huguenin, Sperling, Wiglesworth, Dercum, and many others, I am led to believe that inflammation of the dura mater is not the primary lesion. Denying inflammation as a cause, we are left to accept the doctrine of primary extravasation. Assuming that the grounds for this belief have been made sufficiently plain, we are then confronted with the most difficult problem of all: From whence does the blood in the primary extravasation come, and what are the conditions which bring it about? Its frequent association with alcoholic and terminal dementia, senile insanity, and especially general paresis—Baillarger observed the formation in one-eighth of his cases of paresis, and Wiglesworth in twenty per cent. of his—certainly should direct our attention to the characteristic changes observed in the membranes, vessels, and cortex of those dying with such diseases.

The pathological changes in the tissues mentioned

[6] Journal of Mental Sciences, January, 1888.

may be briefly summarized as follows: An atrophy of the brain as a whole or in part, degeneration of the ganglionic cells and neuroglia of so pronounced a character as to lead Clouston to speak of general paresis as "essentially a death of that tissue, and equivalent to a premature and sudden senile condition, senility being the slow physiological process of ending, general paralysis the quick physiological one."

The vascular changes are as important as constant, the vessels of the pia and cortex being tortuous, looped, varicose, their walls thinned, and the peri-vascular lymph-spaces dilated. All writers appreciate the great vaso-motor disturbances that are manifested clinically and post mortem, and Spitzka places so much weight on these changes as to define general paresis as "a progressive deterioration of the central nervous system, chiefly affecting the brain, and the result of a chronic inflammatory process of an angio-paralytic nature, whose essential element, the vaso motor weakening, is due to over-strain of the encephalic vaso-motor centre," etc.

The membranes of the brain, especially the pia mater, are almost constantly changed, being injected, infiltrated, thickened, and opaque, the vessels giving ocular evidences of their inability to bear the strain put upon them. Leaving the pathological anatomy with this cursory notice, we will consider the relation between these morbid conditions and the subject of this paper. Huguenin argues that atrophy of the brain is an important factor in the production of the hæmatoma, and substantiates his claim by the fact that the greater number of reported cases have occurred in cases in which atrophy was found. He also gives due prominence to the part played by general diseases and grave alterations of the blood.

Wiglesworth follows Huguenin in placing atrophy of the brain, and the consequent loss of support sustained by the meningeal vessels, as a prominent factor in the causation of hæmatoma. He believes that convolutional atrophy favors passive congestion of the vessels, and that they may suffer actual rupture or allow blood to escape by diapedesis. He, however, leaves the exact source of the hemorrhage rather indefinite, and, I think, generalizes too much. Dercum, in the article referred to above, takes a position in advance of Wiglesworth, placing the responsibility of the lesion on vaso motor disturbances. He very correctly observes an analogy between hæmatoma of the dura mater and othæmatoma, attributing both to neuro-angio paralysis.

In this position he is ably supported by Spitzka, who, as we have just seen, looks to this vascular disturbance for the cause of this trouble as well as of general paresis.

The strongest evidence in favor of the causative influences of vaso motor changes is the fact that hæmatoma is found in those psychoses in which we have clinical and post-mortem evidences of serious trophic changes. We have abundant proof of grave degenerations of all tissues, brought about as a result of tropho-neuroses, and hæmatoma duræ is as likely to be caused by these conditions as mollities ossium, othæmatoma, acute decubitus, etc.

There seems to be a general agreement on the part of writers that the primary hemorrhage occurs by diapedesis, or rupture of some of the vessels of the dura mater. Even those who deny the theory of inflammation of the dura still look to the membrane as the source of the primary hemorrhage. Dercum, Seguin, and Spitzka mention the possibility of hemorrhage from the pia mater, but place no great stress upon it. In fact Dercum argues, in support of his theory of rupture of some vessel of the dura, that those which supply dense tissues have, as a rule, thin walls, and for this reason are more prone to rupture when weakened by the withdrawal of vaso-motor tonus. It is a histological fact, however, that the dura mater is composed of two layers, both made up of connective-tissue bundles and elastic fibres; and that the outer layer is the vascular portion of the membrane, supplying the bone above and the internal layer below with blood-vessels. Further, the lower layer has few vessels, and these are very small.

Admitting that the vessels are thin-walled, are they not so because of the support afforded by the dense tissue in which they ramify, and does not this same tissue, which is sufficiently strong to form the great venous sinuses, compensate for the lack of thicker walls? It seems to me that it does, and that these vessels are not as liable to rupture and throw their contents into the subdural space as the thin-walled vessels of the frail pia mater. It therefore appears illogical to look to the dense dura mater for the hemorrhage, and ignore the membrane below, which is composed merely of blood-vessels, lymph-spaces, nerves, and a light trabecula of connective tissue. Especially irrational does it seem when we remember that the pia is so constantly diseased and presents such marked vascular degenerations in the class of cases which furnish the greater number of hæmatomæ.

In conclusion, I wish to suggest the following deductions, offering them as a practical and rational view of the subject:

1. That the disease known as "pachymeningitis hæmorrhagica interna chronica" is not a disease of the dura mater primarily, and not necessarily at all. The name is therefore a misnomer, and the simpler term, "subdural hæmatoma," should be substituted.

2. That the condition is due primarily to a paralysis or loss of the normal vaso-motor tonus, associated with structural changes in the cerebral vessels, particularly those of the pia mater.

3. That hemorrhage may, and often does, take place in the substance of the dura from the causes stated, but that its vascular supply and anatomical structure render it improbable that these hemorrhages play any part in the formation of subdural hæmatoma.

4. That the hemorrhage occurs from the vessels of the pia mater primarily, forces its way without difficulty through the upper cobweb like layer formerly called the arachnoid, escaping into the subdural space. The extravasated blood becomes organized, new vessels are formed, and these assist in furnishing the recurring hemorrhages.

5. That the inflammation of the internal surface of the dura mater is secondary and due to the irritation of the extravasation, and then is not general, but occurs only in patches where organic union has taken place.

Scarification of the Os Uteri in Chlorosis.—Dr. J. Cheron recommends scarification of the os uteri in chlorosis, and points out that this treatment has been highly spoken of by Schubert and others. The amount of blood to be drawn is about one gramme to every kilogramme of body weight. According to the above observers these slight bleedings greatly increase the number of red corpuscles and the amount of hæmoglobin in the blood. Dr. Cheron, in making use of scarification of the os in the treatment of old-standing disease in chlorotic patients, found that the general health as well as the local conditions improved. In many cases an analysis of the blood during and after treatment showed continuous improvement after each scarification. In chlorotic patients congestion of the womb is habitual, and it is easy to obtain forty to sixty grammes of blood at one operation. This local treatment seems likely to be of great benefit to chlorotic women, and it is easy to understand that it would be performed much more readily than venesection. The scarification, if done with antiseptic precautions, is not accompanied by risk.—*The Lancet*, March 5, 1892.

Horse, Donkey, and Mule Meat.—The *British Medical Journal* says that during 1891 the people of Paris consumed 21,291 horses, 229 donkeys, and 40 mules—the meat weighing 4,615 tons. It was sold in the shops at from 2d. to 10d. per pound. Only one-third was sold fresh and undisguised, the rest being made into sausages

PATHOGNOMONIC SIGNS OF PERFORATING APPENDICITIS.

By SIMON BARUCH, M.D.,

NEW YORK.

At the last meeting of the Academy of Medicine this subject received the most practical discussion ever given it in this city.

The lateness of the hour prevented the writer from offering the views herein set forth.

The consensus of opinion seemed to be that most cases of appendicitis should be under the combined care of physician and surgeon. Unfortunately medicinal treatment is too often relied upon until distinct evidences of diffused peritonitis are present, when the surgeon's knife is too late. That many lives have thus been sacrificed is generally admitted.

I have treated quite a number of cases of probable appendicitis without surgical interference. Two of these were recurrent attacks in colleagues, Dr. B——, who was seen also by Drs. Sands, Hackley, and Morris J. Asch, and Dr. W——, who was seen by Dr. Coe. Both recovered after prolonged and continuous use of a wet compress over the right iliac region. Such cases, as well as those which form well-limited abscesses, are not within the purview of this article.

I desire to aid in removing the most active lethal factor in this affection, viz., those cases of perforating (I would call them traumatic) appendicitis which destroy the patient's life within a few days. Of these I have treated five, one in 1881, which was seen also by Dr. Delafield, died in three days in collapse; one in 1883, seen also by Dr. A Jacobi, died in two days, and one in 1884, which was seen also by Drs. Loomis and Weber, died in six days. These were treated by the opiate plan (Dr. Weber proposed an operation on one, which was not done on account of the advanced stage) and determined me to pursue a different course in future.

On December 29, 1889, at 8 A.M., I saw G. W——, who had suffered pain in abdomen all night and had vomited. He had exquisite pain in right inguinal region; pulse, 120; temperature, 102.4° F.; respiration, 36. Fomentations, enemas, followed by $\frac{1}{3}$ grain morphia were ordered. Food and drink withheld. The parents were informed at once of the seriousness of the case and the probability of an operation. On the following morning the temperature was 101.6° F.; pulse, 130; respiration, 30. Tympanites, dulness over appendix; morphine had not been required; pain exquisite only on pressure. Although the general condition was improved I asked for surgical consultation. Drs. Sands and Bull agreed with me on the necessity for operation; this was done by Dr. Sands, Dr. Hartly and myself assisting. A fecal concretion was found just within the grasp of a slit perforation in the appendix; some fecal matter and pus in peritoneum. The edges of the slit were pared and stitched, wound cleansed and packed. Patient made an excellent recovery. Dr. Sands reported this case in full,[1] and regarded it as the earliest operation then on record. Temperature, pulse, and respiration fell within three hours of operation, and improvement was steady from that moment.

Symptoms of shock—cool finger-tips, anxious countenance, and exquisite tenderness—made my diagnosis positive, despite the apparent general improvement on the second day.

The next case, in which these symptoms were absent, may prove interesting also. Miss —— suffered severe pains in inguinal region—menstruation was due. Dr. R——, who was living near her, was hurriedly called in the afternoon and again on the next morning, and stated to me that he found her in collapsed condition and suggested perforating appendicitis. Although she was better when I saw her, and I could discover no evidence of so serious a trouble, I sent for surgical counsel on the strength of this statement of my able colleague. The eminent surgeon pronounced the case undoubtedly one of perforating appendicitis and advised immediate operation.

The symptoms which I regard as pathognomonic of perforation, viz., cool extremities, anxious countenance, pulse and respiration accelerated out of proportion to temperature, and exquisite tenderness being absent, further counsel was suggested. The latter not being obtainable without a delay of several hours, the attending surgeon urged an operation before dark. Patient was etherized and everything prepared, Dr. W. T. Alexander and Dr. O'Neill being present. A vaginal examination satisfied the surgeon that he was in error. The operation was not done. The patient was seen later by Dr. Bull and Dr. Thomas, who approved this course. She recovered and has had no recurrences. Menstruation appeared two days later.

My last case, briefly told, is that of Mrs. R——, who was detained at a summer resort in October, 1891. I was called down by telephone and found that she had been attended for twenty-four hours by a justly eminent city practitioner, being treated for peritonitis by Rochelle salts and morphia. Being compelled to go to Washington, the case was transferred to me, with his consent. Cool finger-tips, anxious countenance, rapid pulse and respiration, with a temperature of 100° F. only. Exquisite tenderness and some dulness in the right iliac region convinced me that this was a case of perforating appendicitis, and led me to urge sending for a surgeon to the city. The latter could not be obtained until after the last regular train had departed. So pathognomonic did I regard the signs present, however, that I insisted upon the friends obtaining a special train without delay (not having instruments and antiseptics myself).

Dr. John A. Wyeth came down on a special engine at 11 P.M. I had in the meantime made the parlor as surgically clean as possible, and gotten everything in readiness for an operation; which was promptly agreed to and done by Dr. Wyeth. The peritoneum was opened, and digital examination for adhesions caused a gush of pus. An elongated nodular and inflamed appendix was found, containing a fecal concretion, whose sharp edge had perforated the appendix. Recent fibrinous exudation and pus mixed with bubbles of fetid gas were found in the vicinity. Dr. Wyeth peeled the appendix off carefully, tied and removed it; washed, drained, and packed the wound. Pulse, respiration, and temperature fell within an hour, all symptoms of shock passed away, and the patient made a good recovery.

What is the lesson to be derived from these carefully observed briefly stated cases?

Symptoms of shock, carefully looked for, may always be found in perforating appendicitis. To recapitulate these—the countenance is anxious, the finger-tips, nose, and ears are cool; pulse and respiration are out of proportion to temperature, the right inguinal region is very tender, the patient usually lies with the right leg drawn up. That these are pathognomonic signs my cases prove. Guided by them I opposed the view of an experienced physician in one case, insisting upon the operation; and in another did not approve the operation advised by an experienced surgeon. In both cases my reliance on these pathognomonic signs proved useful to the patient.

The lesson of these cases, which are fortified by frequent reports of similar ones in our societies, is that when perforating appendicitis is diagnosed, either positively or probably, an immediate operation to remove the exciting cause is as imperative as ligation of the vessel is in hemorrhage.

The fact that laparotomies are now constantly performed, under strict asepsis, with absolute safety, should induce the attendant to clear up a doubtful diagnosis of perforating appendicitis by an operation before septic peritonitis forbids it.

Careful reading of this paper will, I trust, indicate that I do not approve an operation in every case of so-called typhlitis or perityphlitis.

FAVUS AND ITS TREATMENT—RESULTS IN ONE HUNDRED AND THIRTY-NINE CASES.

By SHELDON GUTHRIE EVANS, M.D.,

U. S. NAVY.

Though favus or tinea favosa is an exceedingly rare disease in our own country, it is by no means uncommon in Scotland; and in Germany, where it is known as Wachsgrind, it is of frequent occurrence. I have been fortunate—or unfortunate—enough, within the past few months, to have been brought in close professional contact with one hundred and thirty-nine patients suffering from this disease, all of whom were under the general supervision of Surgeon Abel F. Price, U. S. Navy, the senior medical officer of the ship, and to whom I am indebted for the treatment about to be described. A report of these cases and the method of treatment employed may be of interest to the readers of the Medical Record. With very few exceptions all the cases aboard ship occurred among the apprentice boys, and did not generally extend to the men.

Favus usually attacks the hairy scalp, and in the cases that came under my care all were of this character; and it may be well to state, *en passant*, that it appears to be more severe with those who have light colored hair than with those possessed of locks of a darker hue. It is a contagious parasitic disease, and Schönlein, who was the first to demonstrate that the straw-colored crusts found in the disease, formerly known as porrigo favosa or tinea lupinosa, and which were regarded as the products of inflammation, really consisted of a mass of fungi (achorion Schönleinii).

Microscopically examined, the favi, as the yellowish crusts are called, are found to be made up entirely of the fungus, consisting of "an oval nucleated conidia one thirty-five-hundredths of an inch in diameter; free, jointed or constricted; large, branching, or tortuous mycelial filaments one eight-thousandth of an inch in diameter, filled with granules and spores, and a stroma made up of cellular elements" (Quain).

Hofmann, who has cultivated the fungus, claims that it is identical with the mucor racemosus, but other authorities do not corroborate his views.

Lack of cleanliness seems to be the only predisposing cause of the disease, and dirt a most favorable nidus for the development of the fungi when once implanted. This is, however, by no means true of the cases aboard ship, where the strictest hygienic regulations prevail, and thorough cleanliness, both of person and quarters, is rigidly enforced. The origin of the disease on the ship has been traced to an apprentice boy from Germany, who, when sent to the ship, was evidently suffering from the disease, though it had not fairly manifested itself. From him it appears to have spread to others, mainly through the utensils of the ship's barber, and perhaps, by changing watch-caps, a practice prevalent among the apprentices. As soon as the first case was detected the crew were at once inspected and other cases found.

The disease is characterized by the development of sulphur-colored crusts or scales known as favi. In its first stages we find the affected part studded with fine yellow bodies embedded in the skin. These spots or bodies are, at first, about the size of a pin-head, and each body perforated with a hair. Subsequently they coalesce and the scalp is covered with a thick mass of dirty yellowish scales, having a peculiar pungent and characteristic odor. On removal of the scales we find the scalp reddened, inflamed, and depressed. As the hair follicle becomes overgrown with the fungus, the growth of the hair is impeded, and it soon dries up and drops out. It is not generally reproduced.

Favus is often accompanied by lice, but in none of our cases were these pests found. By a casual observer the disease may be mistaken for impetigo, but on close examination the favi are easily recognized, and the odor is strikingly characteristic.

All writers on the subject say that the treatment is tedious and unsatisfactory, but it gives me pleasure to set forth the method suggested by Surgeon Price, which I have been unable to find in any works now at my disposal, and which treatment has given complete satisfaction. The hair of every patient was, of course, cropped short and kept so during treatment. A solution of bichloride of mercury in alcohol—one to five hundred—was prepared, two stiff brushes provided, and the heads of all the patients were thoroughly scrubbed with the solution every other day for a week or ten days, within which period all the scales were removed, leaving only a yellowish stain upon the scalp. Then a solution of the same strength was prepared with water and glycerine, and the patient's head was bathed therewith twice a week.

Under this treatment all the cases rapidly improved, many have been entirely cured, and none have developed a second attack. If the scalp is very much inflamed and tumefied, a mild sulphur, mercurial, or oxide of zinc ointment will quickly relieve it.

The old treatment, with poultices, etc., would certainly have been tedious, especially with such a number of patients. Should any of the readers of the Medical Record meet with any cases and employ the mercuric chloride treatment, I should be pleased to hear the results.

Progress of Medical Science.

Neuroses of the Prostate.—Dr. Peyer distinguishes three varieties of neuroses of the prostate: 1. A hyperæsthesia of the entire organ; 2, an excessive hyperæsthesia of the pars prostatica urethræ, and 3, the nervous irritability of the muscular portion of the gland, which forms the shut-off muscle of the bladder. The first variety is the most unusual; the second is somewhat more frequent, and the third is the best known. In hyperæsthesia the symptoms consist in an almost constant feeling of irritation in the prostate which often increases to a severe pain. At stool a sexual sensation is often experienced which makes itself felt at the same time in other parts, as for instance the palm or sole of the foot. Any decided pleasurable sensation especially finds an echo in the prostate. Sleep is difficult and not restful; muscular fatigue is quickly produced; there is often congestion about the head and palpitation of the heart. In hyperæsthesia of the prostatic portion of the urethra, which is usually described under the name of neuralgia of the neck of the bladder, the conditions are different. In the rule this hyperæsthesia is not only a symptom of a general neurasthenia, but it is caused by a chronic condition of irritation of the mucous membrane of the prostatic portion, and belongs to the causative conditions of the existing neurasthenia. It is characteristic of this form that the sensitiveness of the nerves to the application of the sound is much greater than in ordinary cases, and that this sensitiveness does not diminish or become blunted by frequent passage of instruments. The third form—the nervous irritability of the muscular elements of the prostate—manifests itself as a rule by a slight cramp of the shut-off muscle, quickly passing away. These patients cannot pass water in the presence of others, nor in the steam cars, and often not at night when tired out or overcome by drowsiness. In a certain number the cramp of the sphincter is a chronic condition, and they can simply never pass their urine at once when they feel called upon to do it. It is always necessary to aid in the act by standing quiet for a time, putting their attention on something else, and avoiding all effort or strain. Others secure the desired result in gently making traction on the urethra until the spasm relaxes. The stream begins slowly, at first only a few drops, and gradually gathers strength. According to Civiale frequent masturbation or too frequent coitus has preceded the affection. According to Ultzmann such a condition may become

localized after a gonorrhœa, as well as a result of onanism. If due to the first, gonorrhœal heads will be found; if to the second cause, the prostatic portion will be very sensitive on passing the sound, and will bleed readily If general neurasthenia is present, a course of treatment to strengthen the whole nervous system is required. If evident local causes are present, application of the sound once a week, remaining quietly in the canal for twenty or thirty minutes, will be of benefit. Local treatment plays the principal part in hyperæsthesia of the prostatic portion of the urethra. After the sound instillations of nitrate of silver often act very beneficially. In all cases regulation of the bowels and of the sexual life is most important. Long walks and horseback riding are to be forbidden. Strong wines, coffee, and tea are to be avoided. Bath and water cures often give good results, but the author has never seen any benefit from electricity.—*Internationale klin. Rundsch.*, January 24, 1892.

Prostatectomy.—Dr. Tobin (*Medical Press and Circular*, December 2, 1891) has successfully practised an operation for senile prostatic enlargement, which consists in first making a small suprapubic incision. A wire doubled and suitably curved is then passed through the urethra into the bladder. A straight sound arranged to receive the wire is then passed till it impinges against the urethral obstruction. The wire loop lying in the bladder is then slipped over the enlarged lobe by means of one or two fingers passed through the suprapubic opening, and while held in place traction is made until it cuts its way through, aided by the counter-pressure of the sound. The following advantages are claimed for this method: 1. As much of the gland as interferes with the escape of urine is removed, and no more. 2. Such portion of it is removed in a satisfactory manner, for the wire starts from the point where the finger defines the obstruction on one side, and cuts up to the point where the instrument does so on the other. 3. A smooth surface, sloping into the urethra, is left, instead of the more or less rough one, that must result from taking away the gland piecemeal with a forceps. 4. There is very little hemorrhage. No brilliant results are to be expected from any operation, and one should be undertaken only as a last resource. When dealing with youth we may talk of a cure; when treating the aged we may consider ourselves lucky if we succeed in making them a little better.

Ephedra Vulgaris is the name of a plant which has long had a reputation among the Russian peasants as an anti-syphilitic and anti rheumatic remedy. Dr. Betchine has recently found that there are just reasons for this, so far as acute articular and muscular rheumatism are concerned. Temperature is reduced, pain relieved, and pulse and respiration lowered, in from one to two days, after dessert-spoonful doses, at two-hour intervals, of a decoction made with a gramme of the powdered root and bark for every five grammes of water.—*Edinburgh Medical Journal*, March, 1892.

The Scarlatinal Bubo.—Drs. Combemale and Lamy have found in a case of cervical adenitis, of scarlatinal origin, going on to suppuration, that the pus, while entering such micro-organisms as streptococci and staphylococci, is not virulent. The microbes appear dead, or are at least deprived of the power of reproduction on nutrient media. Their observations lead them to believe that these microbian agents act more through their toxines, which call forth an abundance of leucocytes.—*Bulletin Méd. du Nord*, January 8, 1892.

Antipyrin in Whooping-Cough.—Dr. Feer (*Medical Press*, January 13, 1892) has recently treated about eighty cases of pertussis with antipyrin, as many decigrammes being given morning and evening as the child was years of age. The beneficial effect was established in four-fifths of the cases. It is not known whether it acts as a germicide or as a sedative, but the balance of evidence inclines to the latter hypothesis.

Therapeutic Hints.

Acute Œdema of the Lungs.—Dr. A. A. Smith has found a most successful combination for the treatment of acute œdema of the lungs to be—strychnine $\frac{1}{30}$ grain and atropine $\frac{1}{100}$ grain hypodermically, and $\frac{1}{100}$ grain nitro-glycerine by the mouth at the same time. The strychnine and nitro-glycerine to be repeated every two hours till relief is afforded.

Ulcerated Chilblains.—Dr. Brogg recommends for ulcerated chilblains:

℞. Acid. carbol. ..... ♏ xv.
Ung. plumbi. ..... ʒ v.
Lanolini. ..... ʒ v.
Ol. amyg. dulc. ..... ʒ ss.
Ol. lavand. ..... gtt. xx.
M. S.: Apply two or three times daily.

Diuretic Action of Diuretin.—Dr. Hoffmann says the diuretic action of diuretin is due to the influence of the drug upon the epithelium of the kidney. He finds that in daily quantity of five grammes it produces no ill effect. It acts where digitalis, strophanthus, and caffeine fail. Cumulative effects have not been noticed, nor does the system appear to become accustomed to its use so that it ceases to produce desired results. Other substances destined to influence the kidneys or heart can be administered at the same time.—*Archiv f. Exp. Path. u. Phar.*, xxviii.

Treatment of Chronic Papillomatous Urethritis.—Dr. Lauz recommends the trichloracetic acid as a caustic in the treatment of chronic papillomatous urethritis, instillations of the following solution being made:

℞. Aq. destill. ..... 100 grammes.
Ac. trichloracet. ..... 20 grammes.

Eczema.—Dr. Hardy considers internal treatment of the greatest importance in eczema after the acute stage is passed, and arsenic as the most important remedy. He gives the arseniate of soda in one-tenth of a grain dose, once daily. Dr. Brocq thinks internal treatment of importance in eczema, and prescribes in strumous cases cod-liver oil or a sirup containing iodine; in rheumatics, alkaline waters; in gouty subjects, colchicum, digitalis, etc. For eczema capitis the following local application is advised:

℞. Naphthol,
Camphor,
Resorcin ..... āā gr. x.
Sulphur ..... ʒ j.
Vaseline ..... ʒ j.

For Pruritus Vulvæ.—Dr. Kholmogoroff cured a case of severe pruritus vulvæ by six applications of galvanism of ten to fifteen minutes' duration, and ten to fifteen milliampères strength of current. The positive electrode, insulated to its distal tip, was introduced four or five centimetres within the vagina, while the cathode, covered with chamois and moistened with a salt solution, is applied over the affected area.

Care of the Teeth in Diabetes.—Dr. Dujardin-Beaumetz says diabetics should care for their teeth and gums with the utmost attention. The following formula for a dentifrice has given him the best results. It is to be diluted one-half at time of using, and should be used twice daily:

℞. Acid. boric ..... 25 grammes.
Acid. phenic ..... 1 gramme.
Thymol. ..... 0.25 centigramme.
Aquæ. ..... 1 litre.

To this is to be added:

℞. Essence menth. ..... gtt. x.
Tinct. anisi. ..... 10 grammes.
Cochineal. ..... q.s. to color.
Alcohol. ..... 100 grammes.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street

New York, April 30, 1892.

EXOPHTHALMIC GOITRE.

BASEDOW'S disease, standing upon its symptomatic tripod of exophthalmos, palpitation, and goitre, has always been an interesting study, not more on account of its widely separated and at the same time intimately associated manifestations, than because of the many features of the disease which were puzzling, and the difficulty of securing favorable results in many cases from known plans of treatment.

There are a few points in the recent literature of goitre, and especially the exophthalmic form, to which attention may profitably be directed.

The pathology of this disease has never been satisfactorily settled, but there has been a decided tendency of late to look for some other explanation than that of disordered sympathetics. White has shown that, while the cells of the cervical sympathetic ganglia are found shrivelled up in exophthalmic goitre, they may also be found in this same condition in health, so that no importance can be attached to this condition in what he regards as degenerated and useless organs.

Dr. Pershing, writing on this subject in the *Denver Medical Times*, March, 1892, regards as more satisfactory the theory which refers the symptoms to disease of the vaso-motor and heart-centres in the medulla. "Most of the symptoms," he says, "such as low blood-tension, throbbing arteries, flushing, sweating, protrusion of the eyes, and swelling of the thyroid gland, may well be attributed to vaso motor paralysis." But the other symptoms, such as rapid pulse, tremor, and occasional paralysis, show, the author thinks, that "the disease is not limited to one centre or to the medulla, but has caused a wide-spread disturbance of innervation." Tremor was a conspicuous feature of the case reported, and this is a symptom which, according to Kahler, is very constantly present. It is distinguished from other tremors by its rapid rate, its regularity, and its small amplitude. While in paralysis agitans and senile tremor the rate is four to six vibrations per second, here it averages eight and a half.

Dr. Sallier has reported an instance of myxœdema complicating Basedow's disease, and a second of œdema. In both cases there was no doubt in the mind of the writer that the mucous œdema was intimately connected with the disease of Basedow.

Unfortunately, little is known concerning the functions of the thyroid gland or body, but it would appear that several affections depend in a great measure upon the integrity and ability of the organ to do its work, whatever it may be. In exophthalmic goitre it is enlarged, often very greatly. In myxœdema the other symptoms would seem to depend in a great measure upon the atrophy of the thyroid, while in cachexia strumipriva the condition follows removal of the goitre tumor by operation.

Moebius thinks the latter condition, as well as myxœdema, are due to suppression of the functions of the thyroid, and Gauthier almost admits the same for exophthalmic goitre, at least so far as concerns a large part of its manifestations. As regards the prevention of cachexia strumipriva, it would seem that the operation known as the Mukulicz resection, by which most of the lateral lobe is taken away, while the recurrent laryngeal nerve is spared, presents the most attractions. In this procedure the portion of the gland-tissue lying next the nerve, which is left behind, appears to be sufficient to ward off the cachexia, so that in 550 partial thyroidectomies done by Berry (*British Medical Journal*, June 13, 1891), only six showed symptoms of cachexia strumipriva, which is usually considered the most important remote effect of thyroidectomy.

In opposition to partial extirpation, Stoker says it is a dangerous operation, exposing to severe hemorrhages, even in simple cases; and because of the danger of myxœdema following it, total extirpation is only justifiable if a portion of the gland is transplanted into another region of the body. If one-half of the gland is removed, the other half atrophies.

Boinet and Gilbert have just reported, in the *Revue de Médecine*, No. 1, 1892, a series of experiments upon the ptomaïnes in the urine of exophthalmic goitre patients; the conclusions drawn from which seem worthy of note.

Three ptomaïnes were extracted from the urine of a woman having exophthalmic goitre associated with motor and cardiac troubles. These ptomaïnes produced upon animals phenomena at times analogous to those observed in the patient. They acted upon the heart, upon movement and sensibility, and upon the temperature. The plain active principle which exists in the products of evaporation of the urine has convulsive properties. Weak doses injected into the veins of a rabbit's ear produced death almost instantaneously. Subcutaneously injected in a frog, this same substance causes slowing and diminished energy of the heart-beats, dilatation of the ventricle, and arrest of the heart in diastole. Each ptomaïne appears to possess peculiar properties, for an account of which we must refer to the original report.

Very little bearing upon therapeutics is to be found in recent writing upon this subject, and until something more is learned about the physiology of the thyroid, and the pathology of the conditions in which it is implicated, little in the manner of rational treatment can be looked for.

We would, however, again call attention to Dr. Fergusson's recommendation of strophanthus, which was published in the RECORD of April 16th, as a means at least of relieving the cardiac symptoms.

Dr. Eloy praises hydrotherapy as a means of diminishing nervous excitability and tachycardia, and insists upon electricity. He also administers arsenic and bromides

alternately, and considers hygiene very important. Dr. Vigoroux (*Gazette aes Hôpitaux*, December 1, 1891) recommends negative faradization of the carotids, the goitre, and the eyes, and positive of the precordial region. After fifteen years of this plan of treatment at the Salpêtrière, carried out in about a hundred cases, it is said that improvement is almost always prompt, and complete disappearance of the symptoms takes place if treatment is persisted in for a sufficient length of time.

The most recent contribution to the pathological anatomy is that made by Mendel in the *Deutsche Med. Wochenschrift*, No. 5, 1892. The few published autopsies which this author has been able to find show the most varied results, from which no safe deductions can be drawn, but it is worthy of note that the sympathetic system was usually found in a normal condition.

MEDICAL PRACTICE IN AUSTRALIA.

A DAILY paper of Sydney, New South Wales, has lately published a series of articles on the "overcrowding" of the profession in that colony. The title of the papers would seem to be somewhat misleading, since the profession in that favored spot is shown to be anything but overcrowded. It is said that there are in New South Wales about six hundred qualified practitioners to a population of 1,134,207, or 1 medical man to 1,890 persons. The incomes with which these lucky men are credited are such as might make their less favored brethren in other parts of the world envious. Several leading practitioners in Sydney are stated to have an income of $30,000 a year; the average income of the rank and file of the profession being from $5,000 to $10,000. *The Lancet*, however, whence we quote these figures, is very sceptical on these calculations, and thinks that the not infrequent breaches of professional manners and methods in that country point to the existence of a much greater pressure of competition than these statistics would lead one to believe.

THE COMMERCIAL ASPECT OF MEDICAL LITERATURE.

OUR contemporary *The Lancet* quotes from a leading article in *The Author*, the official organ of the Incorporated Society of Authors, conducted by Mr. Walter Besant, according to which medical literature rarely brings any direct profit to the author. The writer divides medical books into—1, works of general medical reference; 2, books written in one of a popular series, and 3, monographs on special subjects. The first and second classes may indeed be financial successes; books of the first class often commanding a large sale, while those written as parts of a series pay the author by bringing in some money and some reputation. The good books of a series sell the bad ones, and the popular prices suit the purses of a great many people. The actual amount of remuneration received by the author is indeed usually small; but the work is undertaken, according to the writer, partly with a view to fame, and partly, perhaps, for the sake of not being crowded out of the field by some other person equally fitted for the task. But for the author of books written on special subjects, and not forming one of a series, there is seldom, if ever, any direct pecuniary reward. The circulation of such works is necessarily very limited, and they are often gotten up in a style that calls for a large outlay in the way of colored plates, etc., which would eat up the possible profits of a much larger sale than could ever be attained. The reward is, however, indirect, and is supposed to come in the form of increased consultation practice, reputation, college appointments, and "legitimate notoriety, with its substantial results." *The Lancet* expresses strong doubts as to the substantiality of these results, for, it says, "the laws which govern the growth of fame and of practice are so subtle that they elude definition," yet "their uncertainty has to be faced by all who feel tempted to try the effects of an investment on commission."

THE CASE OF MRS. OSBORNE.

IT is announced by cable from London that the Home Secretary has decided to release Mrs. Osborne, recently sentenced to a term of imprisonment at hard labor, before her accouchement, so that her child may not suffer through life under the stigma of having been born in prison. This is a tardy measure of mercy, for, if the testimony of the lady's previous medical attendants and of those acquainted with her present condition is to be accepted, the woman ought never to have been incarcerated—at least in a common jail.

The *British Medical Journal* has made inquiries of various medical men, and learns from them that Mrs. Osborne has been repeatedly under treatment at various periods of her life, and down to the period of the larceny, and that for attacks characteristic of the highly neurotic temperament, and culminating at times in outbreaks of hystero-epilepsy. The evidence is derived from several independent sources, extending over a considerable period, including the date of the offence for which she is now paying the legal penalty. The *Journal* says that it is not necessary to elaborate the well known fact that the neurotic patient is often a person in whom there are physical causes of temporary mental aberration, and that there is often in such persons a great mental instability which obscures moral issues, and temporarily affects the character and the judgment.

In the article on "Hysteria" in Quain's "Dictionary of Medicine," Dr. Buzzard says: "There is very frequently not only a deficient regard for truthfulness, but a proneness to active deception and dishonesty. So common is this, that the various phases of hysteria are often assumed to be simple examples of voluntary simulation, and the title of the disease refused to the condition. But it seems more reasonable to refer the symptom to impairment of the highly complex nervous processes which form the physiological side of the moral faculties."

Krafft-Ebing says, in his work on "Psychiatrie," concerning the moral defects associated with this affection: "Lessening of the domain of free-will is evidenced by weakening of the moral sense and of the will power, by fleetingness and superficiality of conceptions, by formal and substantial alteration in modes of perception, and in any case by overmastering ideas, and the patient is only the plaything of her own whims, desires, impulses, and imaginations. Thus it may happen that the most important duties are neglected, the holiest feelings outraged."

Our contemporary says that the evidence falls short of legal responsibility, and it does not advance that plea, but there is yet a borderland of insanity which, although beyond the judicial purview, has a real, a painful, and sad existence. In conclusion, the writer says: "This frail, broken, and unstable woman lies under sentence of imprisonment with hard labor, awaiting the still harder pains of labor in a prison; her present condition is one giving room for great anxiety. The chances of life for herself and her child under the existing conditions are not, as will be seen, favorably estimated by her past medical attendants. We do not attempt to weigh the judicial import of the considerations which this history must suggest. No doubt the attention of the Home Secretary will be called to them, and others more specially called to deduce social and legal consequences will deal with them The medical and pathological series of links in the case are, however, sufficiently striking, and our part ends in putting them together for consideration. We must say, however, that in our opinion they make for mercy, and strengthen a plea which is uppermost in many minds for a remission of the term of imprisonment prior to the date of accouchement."

We cannot doubt that this presentment of the medical aspect of the case had had much to do with the determination of the authorities to release the woman, and we congratulate our esteemed contemporary on the successful issue of its appeal for mercy.

STATE AID FOR THE PAN-AMERICAN MEDICAL CONGRESS.

In the previous issue of the Medical Record will be found the circular of information of the Pan-American Medical Congress, issued March 17th, which we advise all our readers not only to peruse but also to keep for reference. If they do not keep it the chances are that, as the time for the meeting approaches, they will wish to recall some of the provisions there laid down, and then they will remember our advice and wish they had acted upon it.

As is there stated, the Congress has been incorporated under the laws of the State of Ohio. This we cannot but regard as a very wise and useful measure, although we believe the American Medical Association has existed for a number of years without having been made a corporate body. The incorporation was at the instance of a well known statesman, who recognized the public and political (not partisan) importance of such a drawing together of men of science from the two Americas, and who believed that the general Government would aid the undertaking in a substantial way were there a body corporate legally empowered to receive and disburse money.

Concerning the propriety of Congress making an appropriation to meet the needs of this meeting there can be, it seems to us, no question. It is an unfortunate fact that the Southern Republics and ourselves have been too great strangers to each other. We are of different races, and hitherto the only bond of union between us was that of a common sentiment in favor of liberty—an abstract idea, and one good for orators to declaim about, but really a pretty fragile bond to unite two such dissimilar peoples. The only way in which true friendship and mutual respect and liking can be promoted between the different nations of this continent is by mutual exchange of visits and consequent personal contact of the individual members of these nations. Nothing is so likely to bring about such acquaintance and promote reciprocal good feeling as a Congress of this kind where all meet on the neutral ground of science, political animosities and social prejudices being laid aside and forgotten. It will not only benefit medicine but it will directly benefit this whole country, and every other country in America which may send delegates to Washington.

It is, therefore, no more than just that the National Congress should aid the physicians who have undertaken this work. We should be in a condition to receive our guests in a becoming manner and to do them honor. As is seen in the regulations, the foreign members are to be charged no fee for registration, the total expense falling upon members residing in this country. It cannot therefore be said that the physicians in the United States are seeking to throw the entire burden upon the country. But as the nation will benefit by the holding of this Congress in 1893, it is but right and just that it should also contribute to make the Congress a success in every way, financially and socially as well as scientifically.

A MONUMENT TO THE LATE DR. SAMUEL D. GROSS.

At the last meeting of the American Surgical Association the following resolution was passed:

"*Resolved*, That the President be empowered to appoint a committee with authority to confer with the friends and admirers of the late Professor Samuel D. Gross, and with the profession at large, for the initiation of a movement, on the part of the Association, having for its object the erection of a monument to Dr. Gross in the city of Washington, D.C."

The committee subsequently appointed consists of Drs. William T. Briggs, Tennessee; Levi C. Lane, California; Solon Marks, Wisconsin; L. S. Pilcher, New York; A. Vanderveer, New York; James McCann, Pennsylvania; D. Hayes Agnew, Pennsylvania; J. Ewing Mears, Pennsylvania; S. H. Weeks, Maine; Hunter McGuire, Virginia; L. McLane Tiffany, Maryland; N. P. Dandridge, Ohio; H. H. Mudd, Missouri; J. Collins Warren, Massachusetts; B. A. Watson, New Jersey; D. W. Yandell, Kentucky; N. Senn, Illinois; Charles B. Nancrede, Michigan; W. H. Carmalt, Connecticut.

The Chairman, Dr J. R. Weist, has issued this circular:

"It is not the purpose of the American Surgical Association to claim the honor of erecting this monument to the memory of one of its most distinguished Fellows; but rather is its intention to initiate a movement in which the entire American profession should feel an equal interest; because Dr. Gross was of no exclusive faction, but a leading member of the whole profession.

"Hence it is, that each member of the committee is instructed to appoint sub-committees in his own State, irrespective of fellowship in this or any other association, which sub-committees will aid him in the collection of contributions to the general fund. Any contributions may be sent to Dr. John B. Roberts, 1627 Walnut Street,

Philadelphia. In the event of a failure to collect a sum sufficient to complete the monument, the contributions will all be returned to the subscribers."

Professor Gross was one of the most conspicuous surgeons America has ever produced, and perhaps no man in his time added so much to the glory of American surgery or the honor of American medicine. No one better deserved the monument proposed, and we trust that the effort to secure it will be successful. Bearing in mind, however, the failure of the attempt to secure a monument for Dr. Rush, we fear that the gentlemen in charge of the matter will have to work very energetically and skilfully. It will not come, experience shows, simply by general appeals, but by personal solicitation.

DR. CYRUS EDSON AS SANITARY SUPERINTENDENT OF THE HEALTH DEPARTMENT.

The appointment of Dr. Cyrus Edson as Sanitary Superintendent of the Health Department is an eminently fitting one, and a just tribute to long and faithful service. From the time he first entered upon his duties as Sanitary Inspector, until his call to his present responsible office, he has not only made himself an authority on sanitary matters, but has displayed an untiring energy in his other work which has borne the richest fruit in initiating and making practical many much-needed reforms of detail management. Particularly has this been the case with the Bureau of Infectious Diseases, of which he has for so long a period been the efficient superior officer. The general public and profession have always rightly trusted in his ability to take prompt and intelligent action in all cases in which absolute protection against the inroads of contagious diseases was necessary, and the present freedom of this city from epidemics, in spite of the many threatened dangers, is an ample guarantee that in his new office his good record will be maintained. We tender him our congratulations and bespeak for him the hearty support of the medical profession, of which he is such a worthy member.

Doctors at the World's Fair.—At a meeting of the committee—consisting of representatives from the different regular medical societies of Chicago, and whose object is to take whatever steps become possible and consistent in the way of entertainment and assistance to visiting brethren during the great Exposition—held at the Sherman House, April 2d, the following permanent organization was effected: *President*, Dr. Charles Warrington Earle; *General Secretary*, Dr. Archibald Church; *General Treasurer*, Dr. A. E. Hoadley; *American Secretary*, Dr. George Henry Cleveland; *German Secretary*, Dr. F. C. Hotz; *French Secretary*, Dr. Ferdinand Henrotin; *Italian Secretary*, Dr. A. Lagorio; *Scandinavian Secretary*, Dr. Ludvig Hektoen. A Russian and Spanish Secretary (and possibly others to represent the principal foreign tongues) will subsequently be appointed. The several secretaries will undertake the work of information, etc., belonging to them, and it is expected that matured plans will soon be announced, and matters connected therewith be in running order. Inquiries are already coming in, and the necessity for proper action is becoming more and more obvious.

News of the Week.

Small-pox.—Two new cases of small-pox and one death on North Brother Island were reported to the Health Department between noon Saturday and four o'clock on Wednesday. James Tully, two and one-half years old, of 1814 Park Avenue, died on Sunday at daybreak. Frank Burke, twenty-eight years old, whose children were taken from 237 East Fifty-sixth Street on Thursday last, developed the disease on Saturday, and yesterday Mary Grady, of 210 East Fifty-seventh Street, was found suffering with the first symptoms. Both patients were taken to North Brother Island.

Ohio State Medical Society.—The Forty-seventh Annual Meeting will be held at Cincinnati, O., May 4, 5, and 6, 1892.

The Forty-Sixth Annual Meeting of the Association of Medical Superintendents of American Institutions for the Insane will be held at Washington, D. C., May 3, 4, 5, and 6, 1892.

The Second Annual Meeting of the American Electrotherapeutic Association will be held in New York, October 4, 5, and 6, 1892, at the New York Academy of Medicine, 17 West Forty-third Street. W. J. Morton, M.D., *President;* H. R. Bigelow, M.D., *Secretary.*

The Middleton Goldsmith Lecture before the Pathological Society will be delivered by Dr. Francis P. Kinnicutt, Wednesday evening, May 11th, at the Academy of Medicine. Subject of the lecture is "New Outlooks in the Prophylaxis and Treatment of Tuberculosis."

It is Reported that Secretary Blaine has placed himself under the care of the wrestler and ex-policeman Muldoon, who will give him, it is presumed, the dietetic and hygienic regimen employed in "training."

Iowa State Medical Society.—The Forty-first Annual Meeting of this Association was held at Des Moines, on May 18th, 19th, and 20th, under the presidency of Dr. George F. Jenkins, of Keokuk.

Minute on the Death of Dr. D. Hayes Agnew, adopted by the College of Physicians of Philadelphia, March 24, 1892. The death of Dr. D. Hayes Agnew, recently President of the College, in the seventy fourth year of his age, and after a life crowned with honor and usefulness, calls for an expression of the sense entertained by the College of the gravity of the loss which it suffers, in common with the profession he adorned, the charitable institutions he served, and the community in which his skill did so much to lessen suffering and death. He began his professional life with no adventitious aids; yet by incessant industry, indomitable perseverance, and singleness of purpose he attained to its highest rank. No temptation distracted his attention from the goal of his life—neither extraneous science, nor general literature, nor the allurements of art, nor the pleasures of society. The undivided strength of his mind and his affections were devoted to enlarging the domain of surgery, not only in its operative methods—which he always subordinated to the welfare of his patients—but also in preparing for his profession a literary monument that might speak for him when his voice should be no longer heard.

His minute acquaintance with anatomy, and his ambidextrous skill enabled him to perform, with ease to himself and safety to his patients, operations which less accomplished surgeons hesitated to undertake. He possessed a certain magnetism of manner, quite independent of formality, that evidently proceeded from the heart, and drew all hearts to himself. Never frivolous, but always cheerful, he was dignified, grave, and earnest, making all who heard him as a teacher and speaker, or in familiar intercourse, recognize in him, above all other things, the upright man. For he possessed eloquence of conviction, and the force of absolute honesty in all his statements, and thereby drew to himself, as enthusiastic admirers and disciples, the successive classes of students whom he taught. The College, desiring to show respect for the purity, uprightness, unselfishness, and modesty of Dr. Agnew's character; its admiration for the noble example of his life; and its sense of the value of his contributions to the science and art of surgery, directs that this minute shall be duly recorded, and a copy of it, signed by the President and Secretary, be conveyed to Dr. Agnew's family. Also, that the College will attend the funeral in a body, and that the President be requested to appoint a Fellow to prepare a memoir of our late colleague.

A New Building for the Post-Graduate School.—The directors of the Post-Graduate Medical School have purchased five lots on Second Avenue, on the corner of Twentieth Street, and will proceed, at no very distant day, to build a capacious, beautiful, and fire-proof building, to contain the Medical School, the Hospital and Dispensary, and the Babies' Wards.

The Late Dr. D. Hayes Agnew, says the *Post-Graduate*, "was for many years a great teacher in Philadelphia, at first in a school of anatomy not directly connected with either of the colleges. At a comparatively late time in life he became Professor of Clinical Surgery in the University of Pennsylvania, but he had achieved his fame before then in a private institution, a school of medicine something like the *extra-mural* schools in Edinburgh. He will always be remembered as associated with our Frank Hamilton, in President Garfield's case. It is generally supposed now that the great uncertainty that existed, until death occurred, as to the track and final lodgement of the ball, would have been much less, had the President been first seen by such surgeons as those who finally had the actual surgical responsibility. When Hamilton and Agnew were called, it was too late to make a thorough examination, without great risks. The final result, however, would have been the same, in any case, for the original lesion was necessarily fatal. Dr. Agnew—like his namesake, the great oculist of New York, Cornelius Agnew, who was in no way related to him—was a man of profound religious character, who had a great influence for good in even a larger circle than his professional life circumscribed. A really great man has fallen in our front ranks. Very few physicians, however eminent, leave an estate of a quarter of a million of dollars, as Dr. Agnew has done. He left fifty thousand dollars to the hospital of the University of Pennsylvania."

The Doctor and the Hotel Clerk.—A good story is told of the late Dr. Thayer, of Burlington, concerning his experience at a hotel in Cincinnati, where he stopped, while attending a National Medical Congress, many years ago. Arriving somewhat late in the evening, he went immediately to bed. Upon inspecting his bill, previous to leaving, Dr. Thayer saw he was charged for a supper the night of his arrival, and inquired as to same, saying he had had no supper that night. "But," the clerk said, "you were here; you *might* have had it." "Oh, well," said the doctor, "I can fix that," whereupon he immediately made out a bill against the hotel for medical services, the amount covering the charge for the supper. Upon presenting the same to the clerk, the latter said: "Doctor, I was not aware we had called on you for professional service." "Oh, no," said Dr. Thayer, "but I was here, and you *might* have done so." The procedure, being so original, so pleased the proprietor that he presented Dr. Thayer with his whole bill, and asked him cordially to make him a visit in the future.—Dr. J. H. Linsley.

American Academy of Medicine.—The following topics are promised for discussion at the seventeenth annual meeting of the American Academy of Medicine, at the Cadillac Hotel, Detroit, Mich., on Saturday, June 4, and Monday, June 6, 1892: 1. "Essentials and Non-essentials in Medical Education," the address of the retiring President, Dr. P. S. Conner, of Cincinnati. 2. "The Value of the General Preparatory Training Afforded by the College as Compared with the Special Preparatory Work Suggested by the Medical School in the Preliminary Education of the Physician," a paper by Dr. T. F. Moses, of Urbana, O. 3. "Does a Classical Course Enable a Student to Shorten the Period of Professional Study?" a paper by Dr. V. C. Vaughan, of Ann Arbor, Mich. 4. "The Value of a Collegiate Degree as an Evidence of Fitness for the Study of Medicine," a paper by Dr. L. H. Menter, of Chicago. 5. "The Value of Academical Training Preparatory to the Study of Medicine," a symposium by Drs. H. B. Allyn, of Philadelphia; W. D. Bidwell, of Washington, and Elbert Wing, of Chicago. 6. "The Newer Medical Education in the United States," a symposium by Drs. W. J. Herdman, of Ann Arbor; Charles Jewett, of Brooklyn, and Elbert Wing, of Chicago. 7. "A Paper on Some Phase of the State Supervision of the Practice of Medicine," by Perry H. Millard, of St. Paul. Members of the profession are cordially invited to be present at the sessions of the Academy.

Stenosis of the Larynx Following Fracture.—The case of stenosis of the larynx, reported at a meeting of the Academy of Medicine, on February 18th last, was presented by Dr. W. K. Simpson, of this city, and not by Dr. C. W. Stimson, as was stated in the published report of the meeting.

The Association of Military Surgeons of the National Guard of the United States will hold its second annual meeting in St. Louis on the 19th, 20th, and 21st inst., under the presidency of Dr. N. Senn. Information in regard to the meeting may be obtained from Colonel E. Chancellor, of No. 515 Olive Street, St. Louis.

Castration in place of execution is suggested by Dr. William A. Hammond as the best method for dealing with murderers.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 9, 1891.

H. P. Loomis, M.D., Vice-President, in the Chair.

Filaria Sanguinis Hominis.—Dr. Samuel W. Lambert presented specimens of the above. The patient was a young man of negro descent, nineteen years of age, and a native of Santa Cruz. In July, 1890, the first symptom was noticed, *i.e.*, a turbidity of the urine, most marked early each morning. The following month he came to New York, and while on the ship all the symptoms disappeared without treatment. He has been here ever since, and has been perfectly well up to November 30th, of this year, when the same symptoms returned. The first urine passed in the morning looks like milk, but that passed at other times is only slightly turbid. He complains of some dyspnœa on exertion, and of gastric distress; his appetite is good, tongue clean, and bowels regular. There are elastic swellings in each inguinal region, which appear to be of lymphatic origin. An examination of the urine showed it to have a specific gravity of 1.026, an acid reaction, and to contain albumin, fat, pus-cells, and a few red blood-corpuscles. No filaria have been found in the urine, and only twice in the blood—at 11 P.M. on December 2d and 8th.

The filaria sanguinis hominis is the embryo of a nematoid worm, first described in 1873. The parent is three and a half inches long, and lives in the human lymphatic system. There are numerous larvæ, which are born alive. The young filaria live in the blood, and appear in the general circulation only at night, although one observer states that if the patient eat during the night the worms appear during the daytime. They may give rise to hæmaturia, chyluria, or both. But little is known of their development after leaving the body. They have considerable vitality, as shown by the fact that those recently taken from this patient, and placed on a slide with only a little paraffine around the cover-glass, have, without further precautions, remained quite active for five days. Eight varieties of filaria have been described.

Dr. Lambert showed the urine which had just been passed by the patient, and remarked that it was more milky than any that he had seen at this time in the evening. He also prepared and exhibited a number of specimens of the blood, and showed the living filaria under the microscope.

Traumatic Rupture of the Stomach and Spleen.—Rupture of some one or more of the abdominal viscera is a comparatively frequent result of severe injury. The solid organs more often suffer, though the intestine is not infrequently the site of more or less extensive laceration. Rupture of the stomach is, however, of considerable rarity, and on this account it has seemed advisable to record the following case:

The patient, a girl about five years of age, is said to have been in perfect health prior to a fall from the fourth-story window of a tenement-house, at about 3.15 P.M. on August 29, 1890. In the fall she struck the fire-escape, and a woman who was standing near broke its force somewhat by an attempt to catch the child. When brought to the hospital, a few moments later, she was conscious, but was suffering from severe shock. Slight hemorrhage from the right ear gave rise to a suspicion of fracture of the base of the skull. She vomited food, but no blood. Soon evidence of abdominal hemorrhage became unmistakable, the abdomen being distended and yielding physical signs of fluid, associated with a more profound collapse, rapid and feeble pulse, and gasping respiration. Stimulants were freely administered both by rectum and hypodermatically, but she rapidly lost strength and died about nine o'clock, five hours and three-quarters after the accident.

The autopsy was performed on the afternoon of the next day, eighteen hours after death, and the following notes were taken at the time: Well-nourished body of a girl about five years of age. Slight bruise on the right side of the forehead. Abdomen much distended and of a greenish color, deeper in spots which resemble severe contusions. No evidence of any fracture. The peritoneal cavity contains considerable gas, and about a litre of dark-brown liquid in which there are bits of partially digested food. The liquid has an acid, disagreeable odor resembling that of gastric juice. Examination of the stomach discloses a large rupture along the greater curvature of the cardia. The opening is about three inches long. On the anterior surface of the stomach, near the greater curvature, is another rupture, but extending in this instance through the muscular layers of the stomach wall only. It is about one and one-half inch in length. Near the pylorus, on the posterior surface, is another, smaller rupture of the peritoneal and muscular coats, with considerable ecchymosis into the surrounding tissue of the stomach. The stomach is empty. No other lesion of the alimentary tract is discoverable. The spleen is somewhat large and soft. On its internal surface, near the lower extremity, is a rupture triangular in shape and about an inch in diameter. The liver is somewhat small and is remarkably bloodless. No other lesion is discovered in it. The kidneys are both of about normal size and shape. In the perinephritic fat, especially on the left side, there is considerable extravasated blood. The capsules of the kidneys are non-adherent, and there is no evidence of disease of the organs, though in places on the surface the stars appear very prominent, suggesting congestion there. The uterus and its appendages, and the bladder, are in normal position, and appear to have been uninjured by the fall. The diaphragm has the normal attachment; no rupture. The heart is normal. At the base of the left lung, on its diaphragmatic surface, are several small extravasations of blood, varying in size up to a quarter of an inch in diameter; subpleural. There is no rupture of the visceral pleura. Lungs are normal. Thymus gland persistent, about two inches long, one and one-half broad. Skull: No fracture or injury apparent over calvarium. After removal of brain and dura careful search fails to reveal any sign of fracture of the base. Brain and membranes are normal.[1]

A case strikingly similar to that here presented was reported in 1870 by Buist.[2] A man fell from a railway trestle to the ground, about twenty feet, his left shoulder striking upon a piece of timber in the fall. He "fainted," but soon rallied and was taken home, and was then able to sit up and converse rationally, his chief complaint being "soreness in the limbs and a fulness about the stomach." At 1 A.M. he was found dead in bed, having vomited a small amount of blood. The autopsy revealed about two quarts of liquid blood in the peritoneal cavity, and beginning peritonitis. There was a rupture on the posterior surface of the stomach, at the pyloric extremity, about five inches in length, extending into the duodenum. "A large clot of solid fibrin filled the rupture." The spleen had a rupture about two inches in length and one-half inch in depth. "All other organs were intact and normal." He had not eaten for several hours, and nothing like undigested food was found in the abdominal cavity. He lived about fourteen hours after receipt of the injury.

It is universally admitted, I believe, that the greater frequency of rupture of the solid viscera in severe abdominal contusions depends upon: 1, Their greater density; 2, their proximity to the bony framework of the body; and 3, their greater fixity. It is easy to understand why a large, dense organ like the liver, lying just beneath the ribs and against the spine, and constrained in this position by the diaphragm, by ligaments, and by

[1] The stomach and spleen from this case are preserved in the Museum of the College of Physicians and Surgeons, Nos. 1470 and 1471.

[2] Buist, I. Somers: Rupture of the Stomach and Spleen from a Fall, without External Evidences of Injury, American Journal of the Medical Sciences, October, 1870.

large vessels, should so frequently suffer. In the case of the hollow viscera, however, the problem is not quite so simple, and two theories have been proposed to account for their rupture. The first maintains that the rupture is the result of sudden increase of internal pressure in the viscus—is, in fact, a bursting of the organ. The second denies this, and holds that the injury is a laceration, precisely like that observed in the solid viscera.

Without entering upon any discussion of the comparative merits of these theories,[1] I desire to state that a number of considerations led me to the belief that the injury to the stomach in the two cases here presented was a laceration, and not a burst. In the first place, the stomach in Buist's case was empty. It is distinctly stated that the man had eaten nothing for some time previous to the accident, and that nothing of the nature of stomach contents could be found in the abdominal cavity. In my own case the stomach could not have been very full, for the accident occurred at 3.15 P.M., probably at least two hours after the completion of the noon-day meal.

The location of the tears, too, is not that which would be expected had the stomach burst. Experiments by Revilliod[2] and Key-Aberg,[3] suggested by the observation of cases of bursting of the stomach (in Revilliod's case as the result of accumulation of gas in a dilated stomach; in Key-Aberg's, by forcible lavage during the treatment of opium-poisoning), developed the fact that the injury in bursting was a slit-like tear along the lesser curvature and parallel to it, both observers agreeing that this is the weakest portion of the stomach wall. In the cases here under discussion, of four tears, none had this situation. Furthermore, in my own case, the largest tear was along the attachment of the gastro-splenic ligament, and very close to the rupture in the spleen, which must be considered a lacerated wound.

The association, in both cases, of the rupture of the stomach with lacerations of solid organs, indicates an amount of compression of the abdominal viscera against some solid structure, probably the spinal column, sufficient to have caused laceration of the stomach.

Finally, the great rarity of rupture of the stomach as the result of contusion argues to me distinctly in favor of the laceration theory of these injuries; for the internal pressure of the stomach must be greatly increased in many cases where the point of contact of the contusing force is below the epigastrium; and still in these cases, while rupture of the intestine is frequent, the stomach escapes uninjured. In the present cases the escape of all other portions of the alimentary tract is suggestive in this connection.

Trichinosis.—Dr. R. G. Freeman presented microscopical specimens showing the trichinæ free in the muscular tissue. The patient from whom the specimen was removed had presented the usual symptoms of trichinosis for about three weeks before death.

Dr. H. P. Loomis presented a microscopical specimen showing the trichinæ encysted, and also a portion of muscle illustrating the gross appearances found in trichinosis. In this case the disease had not been diagnosticated during life, and the specimens were taken from a subject in the dissecting-room. The muscle showed admirably the numerous fine points scattered through it, looking like "fly-blow." The trichinæ were found in every muscle of the body, but they were not so plentiful in the lower extremities as in the diaphragm and the posterior muscles of the chest.

Dr. R. H. Sayre remarked that if the Government made a more thorough and systematic inspection of all meats used for food, such diseases might be in time stamped out.

[1] This question has been ably treated, as regards the intestine, in a paper by B. Farquhar Curtis: Contusion of the Abdomen, with Rupture of the Intestine (American Journal of the Medical Sciences, October, 1887), in which the following conclusions, among others, were arrived at as the result of many experiments: "1. In contusion of the abdomen the intestine is ruptured by being crushed between the contusing body and the bony parts—the vertebræ and pelvis. The injury is therefore not a true rupture, but a contused and lacerated wound of the gut. 2. Partial distention of the gut, especially if a large part of the intestine is distended, diminishes the danger of rupture. If great distention of an isolated loop ever occurred in life, it would increase the danger of rupture, even for a loop not in contact with bony parts. 3. The most exposed position for the gut is in contact with the bony parts—in front of the vertebræ, near the brim of the pelvis (when hernia is present), and near the crest of the ilium."

Correspondence.

THE HEALTH RESORTS OF THE RIVIERA.

(Continued from p. 445.)

V.—General Observations.

(From our Special Commissioner.)

RIVIERA WINDS—LOCAL WINDS—GENERAL WINDS—THE MISTRAL—THE TRAMONTANA—THE GRECO—THE EAST WIND—THE SIROCCO—THE SOUTH WIND—VEGETATION IN RELATION TO CLIMATE.

San Remo, March, 1892.

The present letter is to be devoted to winds and vegetation, both topics of importance to medical men. After that there will be no more General Observations.

A man ought to have a contract to write at least one five hundred-page octavo volume before rashly attempting to say anything decisive about the winds here. There seem to be new winds all the time. And all the old ones object to retiring, just like doctors on hospital medical boards. Moreover, they all seem to like to blow most of the time—that is to say, the winds, not the doctors. Truly the Mediterranean littoral is a region where the air never gets any rest worth speaking about. Outside of Chicago it is probably the windiest part of the inhabitable globe. From a gentle baby-breeze up to a full-fledged storm of fiercest fury, every possible variety of atmospheric current is here encountered.

For convenience sake it will be well to classify Riviera winds under two headings, viz.: 1. Local periodical winds, that occur regularly every twenty-four hours. 2. General winds, that are observed at irregular intervals.

The local winds represent merely the daily interchange of land and sea air. In the daytime the land enjoys a higher temperature than the sea. Hence the current of air is directed landward from the water. At night the opposite state of affairs exists, and the breeze accordingly returns seaward. Hot air always ascends, and cooler air tends to take its place as it rises. The daily recurrence of these winds is thus easily accounted for. It is further apparent that considerable local differences may result from the relative nearness of snow-covered mountain ranges, which must send a cold land breeze down into every unprotected plain. For this reason the noctural land wind at Cannes, Nice, and San Remo, is appreciably colder than along the region from Villefranche to Mentone, which includes Monaco and Monte Carlo. Actual solar heat is just as great at Marseilles as at Nice or at Mentone, but the marked climatic differences between the cities named are in great measure due to the varying intensity of the cold land breezes. The wind from the sea is pretty much the same thing all along the coast-towns of the Riviera. It springs up every forenoon, and is felt until almost sunset. Of course, when a violent gale sets in, in a direction opposite to the prevailing local winds, the latter are swallowed up in the stronger current and lose their influence. But when the storm subsides, the weaker wind once more asserts itself. Now, here again it will be seen how unreliable the thermometer is in regard to climate. Suppose you do have a high "average" temperature, a daily recurring land wind may chill you to the very bone in spite of it; whereas a lower mean temperature may be unaccompanied by these disagreeable, and at times dangerously cold, winds.

On the other hand, it cannot be denied that a constant interchange of air has a salutary influence in preventing miasmatic or zymotic diseases from becoming firmly rooted in these southern places. Whether coming down from the mountains or sweeping across the sea, the air travels through essentially pure and healthy regions. The prophylactic significance of Riviera winds has not, I believe, been duly appreciated by physicians. For the natives are generally huddled together in close quarters, their habits are filthy in the extreme, every hygienic law is constantly violated by them. Nevertheless, one is at once struck by the slight prevalence of those very diseases that ought to decimate the ranks of these careless, dirty, ignorant masses. True, epidemics have not been altogether unknown. But the people live in a way that entitles them to be never without an epidemic. I am thoroughly convinced that if it were not for the purifying winds, most of these Provençal places would soon become uninhabitable. Dr. Onimus is authority for the statement that during the last cholera epidemic at Marseilles the mortality fell by fifty per cent. on arrival of the mistral.

The general winds come from long distances, and their advent, intensity, and duration cannot, of course, be predicted. Still it is known that in certain months certain winds are apt to occur with some degree of regularity. Thus, according to that careful observer, Teysseire, the windiest months are March, April, May, and October, in the order in which they are named. The calmest months are December and January. My own limited observations confirm this statement, which is a kind of accepted Riviera dogma. Unlike other local teachings, this particular one appears to be founded on unimpeachable observations. One peculiar feature deserves mention in this connection, namely, that a wind which at its point of origin is a rain-carrying one, will often bring fine, clear weather to the Riviera. The moisture is evidently dissipated by the extreme dryness of the local atmosphere. Thus it may rain to the north of the mountain ranges, while the sun shines brightly on their southern slopes and valleys.

The mistral, or, as its name implies, the "master-wind," is *facile princeps* among Riviera breezes. It is always a northwest wind, although every violent gale usually gets the credit of being a true mistral. I have already sung the praises of the mistral in speaking of Cannes. It has not changed since then, so far as I know.

The further east we travel the less violent grows the mistral, owing to the intercepting hills and promontories encountered along its route. But it is not a dead wind, even on the Italian Riviera. March is its favorite month, although no winter or spring month can be claimed to be safely without the time-circuit of its visitations. It is an intensely dry and cold wind. Perhaps that is its sole redeeming feature, for a wet mistral would be simply killing.

The tramontana is a north wind, or a north northeaster. It is, like the mistral, intensely cold, but owing to the mountain-barriers in its way it rarely reaches the coast-lands in unmitigated severity. A peculiarity of this north wind consists in that it is often transformed into a southerly wind in those localities where the mountains run down close to the water's edge. A failure on the part of many observers to realize this peculiarity has resulted in much confusion.

An explanation of this remarkable phenomenon is given by Dr. Bennet, about as follows: The north wind reaches the sea at some distance from the beach, owing to the protection granted by the mountains. It leaves the waters inshore calm or nearly so. The sea air that later rushes in to supply the place of the rarefied land air, pushing angry billows before it, is merely the north wind, which having passed overhead and gone out to sea, is pulled back by the mid-day heat.

The greco is a northeast wind, cold, piercing, and very trying to the sick and well. The Western Riviera is less exposed to its biting attacks than the Genoese territory. But it is not, as has been claimed, entirely exempt. Teysseire states that it occurs only about eight times a year at Nice. It is a clear-weather wind coming from countries much colder than the seaboard. Atmospheric vapor is absorbed, not deposited, by the greco. In fact, it may be stated as a general law that winds coming from colder regions bring fair weather on account of absorbing vapors, whereas winds blowing from warmer countries will bring rain, for the opposite reason.

The east wind blowing due east is not often encountered in the winter season. It is more of a spring and summer visitor. Still it does occur in cold weather, and it is then disagreeably cutting. Its velocity is said to be rarely high. But the accessible Riviera records are quite incomplete in regard to reliable information concerning this essential factor, the velocity of winds. It would be well to give some serious scientific attention to so important a detail.

The sirocco, a native of Africa, where its heat is likened to that of a furnace, is a southeaster on the Riviera. It blows oftenest in spring and summer, though, like its predecessors, it is not unknown in the winter months. Rain accompanies or follows it. Dr. de Valcourt calls it the rainy wind of the Riviera. In crossing the Mediterranean Sea the sirocco accumulates moisture. Yeo describes it as warm, wet, and enervating. He could not have more tersely characterized its essential features. You feel all used up after one of its visitations.

The south winds belong to the moist marine variety. They bring clouds and rain. The heavy spring and autumn downpours are generally accompanied by southerly winds. But the direction of the southern current is generally changed to east or west, so that a purely southern wind does not often blow here. Southeast winds are warmer than the southwesterly ones.

"The presence or absence of a plant in a locality says more than would pages of thermometrical observations. Plants, moreover, reveal much more than mere temperature, for they are influenced in life, health, and luxuriance by moisture or by dryness, by wind or by calm, and by the nature of the soil in which they grow." (Bennet.)

As previously intimated, one can study climate through vegetation, and without being an expert botanist it soon becomes apparent to the visitor that the general features of the Mediterranean flora are invariably the same at all the health-resorts of the Riviera.

Now, I do not intend to inflict on your readers a learned disquisition on all the trees and plants that grow in these parts. Those who hanker after that sort of thing will find almost fifty pages (big ones, too) devoted to the "trees of the Riviera," in Dr. Sparks's work. Bennet, too, and most authors, excepting Yeo, present you with more vegetables disguised in Latin garb than you can conveniently digest in a couple of lifetimes. But in the same way that I was compelled to give you a little lesson in geography, you might as well take your brief instruction in botany without wincing. For I don't propose to have anybody tell me that I can't distinguish a telegraph-pole from a eucalyptus-tree, although, especially in carnival time, the moonshine of the early morning hours is a trifle confusing from a strictly vegetarian point of view.

The Riviera is part of the warmer temperate zone, and plants will thrive there that frost would kill. As a matter of fact, every now and then a season of freezing cold does kill off thousands of the more tender flowers, shrubs, and trees. You will have to get way down to southern Italy before a perennial flora of the kind seen here can be found.

The olive-tree is seen all over the south of France, and as it is able to resist frost it does not signify anything in regard to an equable temperature. Still the fact that many Riviera olive-trees contrast by their size and beauty with the dwarfed specimens found elsewhere, may

be interpreted to mean a relatively favored clime. In congenial soil these trees are said to live forever. At Monaco they show you olive-trees that are supposed to have a straight family record, going back to the days of the Roman empire. I fancy some real old American families would gladly exchange their own lineage for that of these trees. The olive makes the agriculturist wealthy, but, as already stated, it says little in regard to climate. It is different with orange- and more particularly with lemon-trees. Where these grow in the open air and permit their fruit to ripen without artificial protection, severe frost has no home. At Mentone, for example, the lemon-tree flowers all the year round, and allows a fine crop of fruit to be gathered four times every year

Fig-trees are allowed to disfigure the landscape to an unnecessary extent in some places. In winter they look beautifully ugly.

But to actually "walk in olive-groves," and "sit under the fig-tree," makes you feel as though some of the Sunday-school talks of early youth had not been altogether wasted on mind and memory.

The tall and graceful eucalyptus-trees have been recently introduced here. They thrive well and grow to an enormous height. I have not yet heard of confirmed malariacs shedding their symptoms while promenading under the shade of the eucalyptus.

The carouba, or locust-tree, is another scriptural acquaintance that you cannot escape from down here. It has been truly named an emblem of evergreen vegetation, and as such speaks well for the local climate. It is a pretty tree to look upon.

Almond, pomegranate-, and especially pepper-trees are old kitchen friends that you naturally like to meet. They don't make you sneeze either, out in the open air, which is considerate, if nothing more.

Thyme and lavender are bushes that likewise have a culinary significance. But they are less frequently encountered than many other shrubs.

To medical men the acacia- (a gum-tree, but not of the chewy kind) and the camphor-tree are also interesting. So is the sharply pointed, porcupiny shrub, growing everywhere and supplying a favorite dinner pill ingredient, the aloe.

"Chian turpentine" trees, likewise, abound here. So does every variety of cancer, the ocular demonstration of an exploded therapeutical dogma.

Oaks, planes, and willows are the principal deciduous trees encountered on the Riviera.

The juniper, the Aleppo pine, the queer-looking umbrella pine, the cork-trees, that look for all the world as though they were under approved modern treatment for elephantiasis, are met with wherever you go.

The oleander, arbutus, myrtle, heath, mountain lavender, and prickly broom are likewise met at most places.

Smilax, ivy, all kinds of ferns, prickly pears, about complete the list of green things that everybody knows, except, of course, garden vegetables. The latter were intended not for the sense of sight and smell, but for that of glut—a very frequent sense at the table d'hôte.

I must not, however, omit to mention all kinds of palms, and the greatly overrated mimosa with its jaundiced flowers. The palms grow in such beautiful profusion that they must really be seen to be truly appreciated.

These, then, are the principal trees, shrubs, and plants which I really know something about, and which are easily recognizable.

But for the sake of some completeness, I might as well mention a few common garden flowers found along the Riviera. I will take Dr. Bennet's list. Not because it is in Latin, but because he took it, I presume, from some expert botanist, who in his turn cribbed it from some older author, who probably did not invent it either. We all do that sort of thing, when we feel sure nobody is looking. And before Adam we are all even—ancestors, contemporaries, posterity—the whole strange rigmarole called life and death, or history, or fact, or fiction, or anything you choose. Let us, therefore, not despise the flower in its bloom, and if it grows so plentifully that they do extravagant battle with it, let us be duly thankful. It really needs a *bataille des fleurs* to convince the sceptic what a multitude of beautiful flowers grow here in riotous luxuriance. And then, too, flowers are the only really cheap thing on the whole Riviera.

But here is the list: Cactaceæ in general, mesembryanthemum, iris, maritime squill, cineraria maritima, alyssum, rosemary, thyme, wallflowers, stocks, carnations, marguerite, geranium, pelargonium, marigold, arabis, silene pendula, primula (common and Chinese), violets, pansies, nemophila; hepatica, roses, chrysanthemum, salvias of many kinds, lavender, mignonette, fabriana imbricata, justicia alba, tobacco, red valerian, daphne, spirea, achillea, veronica, erica mediterranea, nasturtium, habrothamnus elegans, lantana, abutilon, datura stramonium, linum trigynum, sparmannia africana, petunia, cyclamen, camellias, azaleas, calla æthiopica, richardia æthiopica, wigandia caracasana, bignonias, begonias, cineraria, verbena, cytisus, cistus, many species of passion-flowers, chorozema, and most Australian winter-flowering mimosæ and acaciæ; spring bulbs—crocus, snowdrop, hyacinth, ranunculus, narcissus, ixia, sparaxis. Most of these plants can rest in the warm dry summer without being injured thereby. They are all, or nearly all, perennial in this climate. They start into life with the autumn rains, flowering more or less early in the winter or spring, and most of them continue in full bloom from Christmas to April, a month which, horticulturally, corresponds to June in England.

If I have inadvertently omitted to mention any pretty flower, or ugly bush, or stately tree, I regret the fact more sincerely probably than the reader. But I can make no rash promise to write a vegetable supplement later on.

Alcoholism and Tuberculosis.—Dr. Hector W. G. Mackenzie, assistant physician to the Brompton Hospital for Consumptives, is of opinion that tuberculosis is much more common among those addicted to alcohol than is generally believed. He says that his experience among the out-patients at the Brompton Hospital is that a considerable portion of the phthisical—especially of the men—have been alcoholic, and that a history of alcoholism is a very common antecedent in those cases where there is no inherited susceptibility to tubercle. As regards women, it is impossible to say to what extent alcohol is responsible for the disease, it being very uncommon for a woman to own to alcoholic habits. He finds that in alcoholic cases the condition of the patient is generally worse than would be expected from the amount of disease revealed by physical examination. It is therefore specially important in such cases, when there are any chest symptoms, to examine the sputum for bacilli. By this means he has been able to make an early diagnosis of phthisis when the examination of the chest was negative. In alcoholic cases the progress of the disease, as a rule, is rapid, and the prognosis particularly unfavorable. Dr. Mackenzie does not offer an explanation why many drunkards develop phthisis. Our observation leads us to the conclusion that in the majority of cases of phthisis in inebriates the patients have endeavored to live on alcoholics in lieu of food. Everyone admits the importance of malnutrition as a factor in the causation of tuberculosis, and it is not a matter for surprise that drunkards who habitually neglect their food frequently die of phthisis.—*Hospital Gazette.*

A Pacific Association of Rhinology, Laryngology, and Otology.—It is proposed to form a society of practitioners residing west of the Rocky Mountains who are especially interested in diseases of the nose, throat, and ears. The society will be organized at the time of the meeting of the California State Society, in San Francisco, on April 19th.

OUR LONDON LETTER.

(From our Special Correspondent.)

CONCLUSION OF THE DEBATE ON PHAGOCYTOSIS AND IMMUNITY AT THE PATHOLOGICAL SOCIETY—SPEECHES BY DR. RUFFER, MR. BALLANCE, MR. HANKIN, DR. SIMS WOODHEAD, AND SIR GEORGE HUMPHRY.

LONDON, March 19, 1892.

THE debate at the Pathological Society on phagocytosis and immunity was resumed again on Tuesday evening last and brought to a conclusion. Dr. Ruffer opened the adjourned discussion and confessed himself to be so far a disciple of Metschnikoff that he accepted his theory in its entirety. He remarked that not one of the speakers had explained what he meant by immunity. There was, he said, no animal, whether naturally resistant or protected by artificial means, which could not be killed by the introduction of a specific microbe, provided a sufficiently large dose were used. To talk of an animal being immune against a given microbe was to speak of something which did not exist, and he would rather speak of animals as being naturally resistant and artificially protected respectively. In both cases he believed that the destruction of micro-organisms was accomplished by the amœboid cells termed phagocytes, but he was not aware that Metschnikoff, or any of his pupils, had ever said that this was the only cause of the increased resistance of such animals. Dr. Ruffer explained that he had not himself said anywhere that all microphages, epithelioid cells, etc., were derived from leucocytes; what he had said was that in the cases he had observed the microphages were derived from small lymphocytes. There could be no doubt that leucocytes had the power of taking bacilli into their interior, and that the organisms underwent some kind of destruction. Any one who possessed a good lens, a drop of frog's blood, and a few anthrax bacilli, could observe this for himself. Dr. Klein had laid stress on the fact that, in several instances, the process was reversed and the leucocytes were destroyed by the bacteria, and he had urged that this was a fatal objection to Metschnikoff's theory. In almost every one of his (Dr. Ruffer's) papers, however, he had specially mentioned that a large number of amœboid cells perished in the fight; he had shown this to take place in the healthy rabbit's Peyer's patch, in the diphtheritic membrane, in actinomycosis, in tubercle, in charbon symptomatique, etc. He was willing to allow the accuracy of Dr. Klein's experiment when, on injecting a quarter or half a syringeful of fluid containing anthrax spores or anthrax bacilli, he found the anthrax bacilli in the blood a few minutes afterward. It would be wonderful if it were not so, for the frog's phagocytes could arrest a certain number of bacilli, but not an immoderate number. Dr. Ruffer said he had shown in one of his papers that in animals exhibiting some resistance against the bacillus of Chauveau, the disease was strictly limited to the point of inoculation and its immediate neighborhood; when, from any cause, the amœboid cells were prevented from approaching the virus, the disease became general and the animal died. It was easy to prove that in an animal anæsthetized by subcutaneous injections of chloral hydrate the leucocytes were inactive. He had vainly sought for any evidence to show that the fluids of chloralized guinea-pigs were better cultivating media for the bacillus pyocyaneus than those of a non-chloralized animal; in both chloralized and non-chloralized animals the bacilli seemed to thrive exceedingly well in the fluids of the living body. This was another instance of the part taken by phagocytes in the limitation of the disease. It had been proved that the substances which attracted the amœboid cells toward the virus were the poisons secreted by, or contained in, the micro-organisms. It was probable that in some cases these poisons might have the opposite effect, viz., that of repelling amœboid cells. Dr. Ruffer described some experiments he had made which seemed to show that the same substance might attract or repel leucocytes according to its state of concentration. When once the poison secreted by a particular micro-organism had penetrated into the system, it would appear as if in many cases the leucocytes had lost the power of leaving the blood-vessels in order to attack the invading micro organisms. This loss of power was not always due to a paralysis of the cells, as these still emigrated freely in order to attack certain other bacilli but resulted from some other cause still shrouded in mystery. Phagocytes exerted a distinct choice between two kinds of microbes. They would leave the bacillus of tetanus for the micro-bacillus prodigiosus, and the streptococcus for the bacillus of diphtheria. This was well illustrated in the diphtheritic membrane, where at the surface one could see leucocytes taking in numbers of bacilli, but leaving streptococci almost untouched, with the immediate result that streptococci were often met with in the deeper parts of the membrane, and with the remote result that secondary abscesses occurring in the course of diphtheria were never due to the bacillus of diphtheria but to some other micro-organism. The study of the diphtheritic membrane showed the remarkable resisting powers of leucocytes, for although the tissues underlying the membrane were necrosed and dead, the leucocytes had the power of marching in numbers right up to the bacilli and waging war against them, although, as he had shown, many perished in the fight. He could not agree with Buchner that the fluids of a living animal played any part in killing bacilli. It was a most remarkable fact that if the serum of an animal was found to possess the power of killing any germ, yet that same microbe, if injected into the living tissues of that animal, would flourish and multiply; the only exception he knew to this was the white rat, which was not only resistant against anthrax but its serum was also bactericidal to that microbe. There was no relation between the bactericidal power of serum and the resistance of the animal to the micro-organism. It had recently been shown that the serum of animals protected against the pneumococcus was a far better cultivating medium for that organism than the serum of animals not so protected. It was easy to understand why micro-organisms became more virulent when passed through resistant animals, for a process of elimination took place, the weaker germs being killed, and only the more hardy surviving. There was no evidence that the fluids of a living resistant animal took any share in attenuation of virus, and he believed that the only process essential to resistance, or so called immunity, was the power the cells possessed of taking micro-organisms into their interior and destroying them.

Mr. Ballance said the question of immunity had an especial interest for surgeons, whose daily occupation was the making of wounds which, if not rendered immune against the attacks of micro-organisms, might seriously imperil life. The observation of the manner in which nature removed foreign material in wounds would to some extent aid in the study of similar processes when engaged in warfare with disease, for it was not to be supposed that the tissues were supplied with various weapons, each designed to repel the attack of a different foe. In conjunction with Professor Sherrington he had studied the question of repair by introducing small Ziegler chambers into the subcutaneous tissue and peritoneal cavity of certain animals. As the result of their observations, they concluded that the invading leucocytes had only a temporary purpose to fulfil in the healing of a wound, and that the number invading the tissues was to some extent adapted to the nutritive requirements of the amœboid connective-tissue corpuscles, whose food they constituted, and which alone spun the connective tissue that repaired the wound. The rush of leucocytes which occurred toward a spot invaded by micro organisms might, however, be useful. They might, though of feeble vitality, be able to digest and destroy certain of the foreign organisms. By the death of others a ferment might be set free which might diminish the vitality of some of the

bacteria, and thus cause them to be an easier prey of other cells. Abundance of food (leucocytes) for the after-coming connective-tissue corpuscles would be associated with the attainment by them of the highest degree of vigor and vitality. Mr. Ballance said that all the main work in wounds—not only with regard to repair, but with reference to the removal of foreign bodies, such as clot, ligatures, micro-organisms, etc.—appeared to fall upon the connective-tissue cell, and he adduced a number of facts which told against the view that the leucocytes were tissue repairers. The amœboid cells of the body had been observed devouring in their food vacuoles, various kinds of food, and various foreign material. The further question arose, What action had they upon substances outside themselves? In other words, did they give to the fluids they lived in a fluid or ferment which could act upon uncoagulated, unshielded proteid in the same way as the fluid of a food vacuole? He thought the answer must be in the affirmative, and that the alleged bactericidal power of the body fluids might thus be explained. The death of leucocytes, which was always occurring, might be thought of as setting free into the body fluids fibrin ferments—a body which must be closely allied to Hankin's anti-toxic substance and Wooldridge's tissue fibrinogen. The normal physiological activity of the cells of the body might thus possibly explain the defensive action of the healthy tissues and fluids against bacterial infection. The question was essentially a chemical one.

Mr. Hankin said that on the one hand there was a body of evidence that appeared to be irrefutable in favor of the view that phagocytes played an important part in the production of immunity. On the other hand, the supporters of the so-called humoral theory had shown that in several cases an increase of the bactericidal power of body fluids accompanied the acquisition of immunity. It was unphilosophical to suppose that the latter change was merely of the nature of an epiphenomenon. There were a number of cases in which, if an animal were inoculated with a microbe against which it was naturally immune, the microbes multiplied till the phagocytes arrived on the scene. There were also a number of cases in which the phagocytes attacked the microbes and were then destroyed by them. Thus an animal was only immune against a disease if its phagocytes were immune against the microbe. Why were the microbes victorious in one case and the phagocytes in the other? The discovery of alexius suggested an answer to this question. If the phagocytes were victorious, it was because a particular alexin was present that had the power of destroying the microbe. It could be shown that the bactericidal power possessed by body fluids after death was absent from them during life. This strongly suggested that the bacteria-killing activity of blood serum, for example, was due to substances (alexius) derived from cells after the blood had been liberated from the body. In other words, the absence of bactericidal power from the body fluids during life could be explained by the intactness of the phagocytes and other contained cells. Mr. Hankin discussed at some length various objections to this view which had been put forward.

Dr. Sims Woodhead then replied. He observed that the term "immunity" was used in two different senses in clinical and experimental work. A patient was only exposed to the ordinary chances of infection, as usually understood, whereas an animal in the hands of the experimenter was subject to very different conditions, as, for instance, when injected with an organism of specially virulent growth. It was well known that, under suitable conditions, an organism might become much more virulent than usual. In the case of the tubercle bacillus, tuberculosis could be produced with great certainty in an animal ordinarily insusceptible to the bacillus if the organism were injected into the peritoneal cavity. He thought specificity was to a great extent a question of phagocytosis, and that if an animal was immune it was due to phagocytosis. Professor Klein's case of injecting innumerable anthrax bacilli into the lymph sac of a frog had no analogy. As Metschnikoff had stated, the phagocytic power of the leucocytes might in certain individuals be imperfectly developed. With regard to the main question, all the positive evidence was in favor of phagocytosis, so far as the earlier stages of infective diseases were concerned, and it was the only theory on which both the experimental and clinical evidence could be explained. There was no real evidence for the humoral theory, for results obtained with serum which was a product of dead blood could not be assumed to hold good for living blood. He could not agree with Klein's statement that bacilli got into the leucocytes to avoid the bactericidal blood plasma, for many of them were non-motile, and could not possibly push their way into the leucocytes.

The President (Sir George Humphry) then closed the discussion. He remarked that the general tendency of the discussion had been to establish the existence of phagocytosis. The leucocytes generally succeeded in absorbing the microbes, unless the latter were too many or too virulent for them. The chemical questions were much more difficult and uncertain. The question of exhaustion had not been touched. No theory of phagocytosis was capable of explaining why a catarrh, after attacking one part, left it and proceeded to attack other parts. Why, when the microbes of small-pox or of scarlet fever were apparently in full possession, should subsidence of the diseases occur? Was it due to some self-engendered poison, or had they exhausted the pabulum?

THE GUILD MISERICORDIA.

To the Editor of the Medical Record.

Sir: The Medical Guild of Misericordia is a society of medical men, practitioners and medical students, interested in the work of mercy for the sorrowing and the suffering. The Guild comprises an order of brothers and associates—the former communicants of the Episcopal Church, and the latter members of *any Christian* denomination. The great cause of medical missions has never received attention in the United States or anywhere else in Christendom since the days of early Christianity. The Misericordia is designed to develop, so far as possible, the invaluable opportunities which exist for extending Christ's kingdom on earth through the aid of medical missionaries. More so than any other, the profession of medicine—so highly blessed by divine recognition, should stand ready to aid the Church, not only by affording scientific witness to the truth, but also by practical works of mercy for His sake—continually remembering the example of Him who went about doing good. It also aims to afford professional relief in urgent cases to the worthy poor. The Guild desires to have representatives in every city and town, and especially in mining regions, railroad centres, etc., so that in case of sudden and appalling disaster, like that in Johnstown, Penn., the work of relief may be intrusted in the care of members of the Guild and speedy aid and comfort be thereby attained. It is a noble work, giving emphasis to the life of all medical men, who are so well known for charity the world over. Full particulars may be obtained by addressing The Guild Misericordia, P. O. Box 1405, Beverly, Mass.

W. Thornton Parker, M.D.

The Vienna Medical Society.—At a recent meeting of the Imperial Royal Medical Society of Vienna, Professor Billroth announced that 9,000 florins had been subscribed for the erection of a building to be used as the permanent home of the organization. Of this amount the Emperor gave 5,000, and a lady who wished to remain anonymous gave 4,000. The individual members of the society then subscribed a sufficient amount to secure the erection of the building.

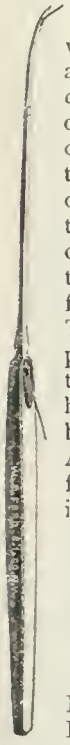
New Instruments.

A NEW SURGICAL NEEDLE.

By GEORGE PLACE CLEMENTS, M.D.,

NEW YORK.

I DESIRE to call the attention of the medical profession to a new needle that I have devised for the purpose of introducing a silver-wire suture in operations for repair of cervix or perineum, or wherever a silver-wire suture is required. The needle is hollow, and curved near its point, as seen by the cut. An opening is formed in the handle for the entrance of the wire. It is so constructed that, should the curved needle break, a new one could be attached to the holder. The wire should be cut the length desired, and one end inserted into the opening in the handle, and pushed forward near to the point of exit. The needle is then driven through the tissue and the wire passed along until it emerges far enough to be grasped by forceps or fingers. The needle is then withdrawn, leaving the wire in position. In this way the wire is placed in position direct, without the use of silk or needle-holder. The instrument is manufactured and sold by the Ford Surgical Instrument Co., of 313 Fifth Avenue. My thanks are due to Mr. C. F. Ford for the interest he manifested in carrying out my idea and producing a perfect needle.



TROCAR AND DILATING CANNULA FOR ABSCESS DRAINAGE.

By J. JULIO HENNA, M.D.,

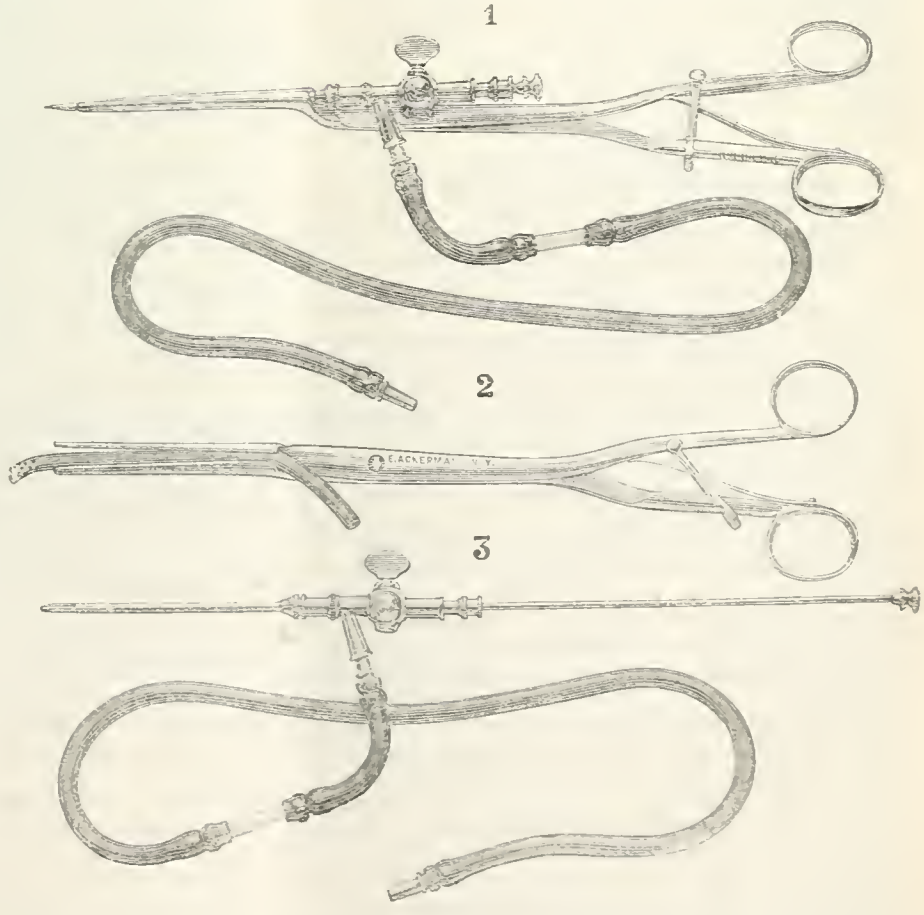
SURGEON TO THE FRENCH HOSPITAL, NEW YORK.

My attention having been called to Dr. Bache Emmet's drainage trocar (MEDICAL RECORD, March 19, 1892), I herewith beg to submit an instrument which I devised in February, 1891, and which I have ever since used in the French Hospital and in private practice. The idea occurred to me while helping my colleague, Dr. W. Duncan McKim, at the hospital, to operate on a large pelvic abscess, by means of that most unfit and dangerous instrument the scissors.

The new instrument, which I have named "trocar and dilating cannula for abscess drainage," gives the surgeon entire command over the field of operation, besides the advantage of inquiring into the quality of the fluid contained in the sac, after which he can choose between aspirating and washing out, or dilating and draining, without exposing his patient to the many incidents prone to occur with the scissors, such as hemorrhage, false passages, injuring the walls of the abscess, etc. The three plates and the description of the mechanism, I hope, will convey a clear idea of the simplicity of the instrument. As implied by the name, it consists of two distinct parts, a trocar, No. 3, and a dilating cannula, No. 2. The trocar portion may be described as consisting of the following parts: 1. A trocar proper, the spearhead of which has a greatest diameter of one-sixteenth of an inch, with its facets bevelled posteriorly to facilitate withdrawal, and the shaft expanding at the proximal end into a disk, where the thumb is applied to effect the perforating thrust. 2. A cannula, three and three-quarter inches in length, tapering slightly at its distal end, where it is split into four leaves, to increase the elasticity of its embrace about the passing head of the trocar. 3. A short tube, to be screwed to the cannula, provided with a vent-pipe at its distal end for the attachment of rubber-tubing, a stop-cock at its middle, and an orifice at the proximal end for the passage of the trocar. The dilating cannula resembles, in many respects, an ordinary uterine dilator, consisting of two blades which are caused to separate by an approximation of the handles. The blades are concave on the inner surface and convex on the outer, so that, when in contact, they form, externally, a long truncated cone of very gradual taper, the base being toward the handles, while internally there is formed a canal. The two shanks are held together by a pivot-joint of the kind in common use for scissors and artery-forceps. There is an elastic steel arm between the handles, serving as a spring, whereby the blades are kept in constant contact. A kind of yoke passes from one handle to the other, through adjustment of which the handles may be rigidly fixed at their greatest separation, which means an immovable contact on the part of the blades. By sliding one end of this yoke along a ratch, the blades may be fixed at any angle of divergence. The greatest separation of which the blades are capable is, at their distal ends, about three-quarters of an inch.

The parts of the instrument are all quickly detachable and easily cleaned, so that a condition of asepsis is readily effected.

The use of the instrument, in a case of pelvic abscess, may be thus described: The blades of the dilating cannula are separated, the cannula with included trocar is laid within their grooves, the blades are again approximated and so held by the handle-yoke, whereby the trocar cannula is firmly grasped, and the unity of the instrument



is complete. The trocar point being well withdrawn into the cannula, the end of the dilating cannula is advanced along a finger within the vagina to the point of intended puncture. The handle of the instrument being held in the palm of the right hand, the trocar is now thrust into the abscess by pressure of the thumb. The elastic embrace of the cannula end offers some little resistance to the onward motion of the trocar head, but as the passage is completed there arises thereby a spring-like momentum which facilitates penetration. The dilating canula is now pushed on into the abscess cavity, the trocar is withdrawn to its full extent, the stop-cock is turned, and the abscess fluid escapes along the vent-pipe and rubber-tubing, in the course of which latter there is an interposed glass tube through which the nature of the fluid becomes apparent. If it be desired, now, to make permanent drainage, the blades of the dilating cannula are separated, the trocar cannula is removed, and through the opening maintained by the divergent blades, a rubber drainage-tube is easily introduced into the cavity of the abscess.

This instrument was made for me by E. Ackermann, 153 West Twenty ninth Street, New York.

8 West Fortieth Street, New York.

The Congress of Criminal Anthropology in its Relations to Sociology and Biology will hold its third meeting at Brussels from August 28 to September 3, 1892. The following is the programme of subjects for discussion: "The Physical, Intellectual, and Moral Characteristics of Born Criminals; Is there an Anatomical Type distinctive of Criminals?" "Suicide and Insanity in Criminals;" "Influence of Simulation on the Production of Genuine Attacks of Insanity;" "Physical and Economic Influences of Criminality;" "Applications of Criminal Biology and Sociology to Legislation and Jurisprudence;" "Determination of the Psycho moral Worth of Parties in Civil Processes;" "Relapse and Premeditation in their Relations to the Suggestions of Social Surroundings and Individual Obsessions;" "Criminal Suggestions;" "Characteristics of Criminality in Children, Adolescents, and Old People;" "Characteristics of Criminality in Woman;" "Necessity of Regarding the Psycho-moral Examination of Certain Prisoners and Defendants as a Duty on the Part of the *Juge d'Instruction;*" "Incorrigibility, its Characteristics and the Measures of Repression which it Admits of;" "Measures to be Taken with Regard to Offenders Suffering from 'Moral Insanity,' to Lunatics who have Committed Crimes, and to Criminals who have become Insane or have been Recognized as such while awaiting Trial;" "Influence of Professions on Criminality;" "Criminal Morbid Obsessions;" "To what Extent is it Necessary or Desirable to Undertake the Study of Criminal Psychology or Psycho-pathology in Prisons?" "What Measures should be Taken as Regards Incorrigible Offenders and Habitual Offenders, and what is the Proper Authority to Decide about Them?" "Collective Offences; Criminality of Crowds and of the Sexes."

The Opium Controversy.—It is with opium as with alcohol. We are continually hearing from opposite stand-points "the truth" about it. As yet, however, the unpractised hearer, however candid, finds himself so beset with contrary arguments that he has little chance of arriving at an exact opinion on the subject of its use or its abuse. We had occasion recently to notice the significant fact that a memorial condemnatory of the growth and sale of the drug, as now permitted by the Indian Government, had received the signatures of some five thousand British medical practitioners, a considerable number of these having had, we may state, personal observation of the opium habit as practised in China or India. On the other hand, we have a mass of official Indian testimony, largely drawn, moreover, from non-medical sources, which is opposed to the view that the use of opium has gravely prejudiced the health of our fellow-subjects in that country, that it is decidedly increasing, or that its manufacture there has any marked influence on the maintenance of opium-eating and smoking in China. According to this evidence, not only is the drug, if used in moderation, not injurious, but it is in some cases—notably those of persons exposed, as in Assam and Eastern Bengal, to damp and malaria—positively beneficial; it is conservative of physical endurance, it enables the consumer to live healthily on less food than he would otherwise require; it does not, as asserted, cloud his mental faculties, and, even if hurtful, it is so by reason either of adulteration with Indian hemp or of excessive indulgence. They assure us also that the Chinese objection to its importation is only pretence, and intended to protect the privileges of native producers. We observe, however, that even these advocates of its utility do not deny the capacity for mischief possessed by opium if indiscreetly taken. Neither do they dispute its essentially and strongly poisonous character. They show, moreover, no direct or indirect advantage worth naming as arising from its consumption, unless in the presence of illness or as a preventive of malarial infection. These facts, in our opinion, are quite sufficient to justify its restriction to purely therapeutic uses, the more so that it is, if we may trust the teaching of modern observation, by no means the best safeguard against malaria. As regards the attitude of the Chinese Government, we may note a statement by the Viceroy Li Hung Chang, in 1881, in which he resents on moral grounds the encouragement given by this country to the opium habit in his own, and declares that the opium war must be taken as China's ineffectual protest against our action. Our ambassadors to China, Sir Rutherford Alcock and Sir Thomas Wade, unlike some critics less favored as to means of observation, were convinced of the sincerity of these protestations. In Burmah, it is said, matters are coming to a condition no more hopeful than that of her greater neighbors, foreigners and the natives alike indulging freely, and with obvious injury to health and morals, in the same seductive habit. In the face of such facts as these we confess that we can see but one way of escape from the difficulties which surround this question—that is, the legal restriction of opium to its use for purely medical purposes.—*The Lancet*, March 5, 1892.

Damages for Lost Grafts.—A novel action for damages in reported to be pending somewhere in the German Empire under somewhat curious circumstances. A nurse allowed skin grafts to be snipped from her lily white arm in deference to the wishes of the patient and the request of the surgeon. Unfortunately, the wound did not heal, as might have been anticipated, but proved the starting-point of a cellulitis, causing great suffering, permanent disfigurement, and some loss of function. The nurse consequently feels aggrieved, and claims damages from the surgeon.—*Medical Press.*

TWO NEW CLAMPS FOR USE IN ABDOMINAL SURGERY.

BY R. MARTIN GIL, M.D.,

MEDICAL DIRECTOR OF THE HOSPITAL "NOBLE," MALAGA, SPAIN.

IT is a very general opinion among gynecologists that in the technique of ovariotomies intra-peritoneal treatment should be preferred, and that entire or partial ligatures of the pedicle, cauterizations, sutures, etc., should be done away with, in order to avoid subsequent hemorrhages, which not alone expose the operation to ultimate failure by retarding healing, but also frequently endanger the lives of patients.

Intra-peritoneal treatment of the stump certainly marks a great advance in abdominal surgery, for the reason that by it general and local infection, hernia, and eventrations are avoided; but this treatment cannot always be followed, and it often happens that special circumstances connected with the pedicles require an extra-peritoneal operation (Hegar and Kaltenbach).

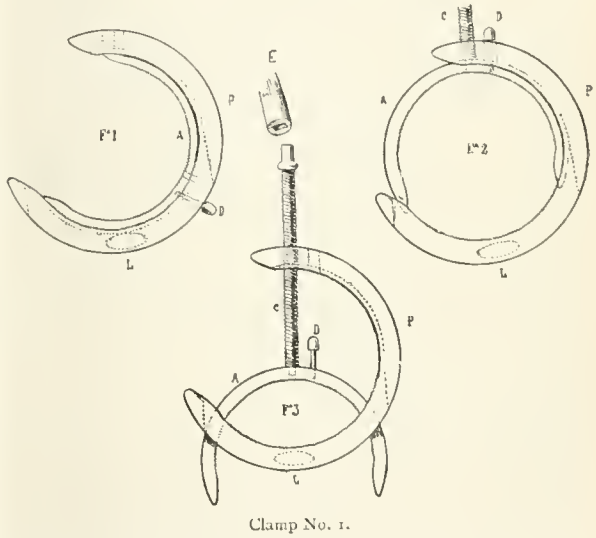
Lawson Tait advocates this method of treatment when the pedicle is very soft and there is danger of secondary hemorrhage when the vessels are cut by the silk threads.[1] Other operators, such as Thomas Keith, employ the clamp provisionally while cutting the pedicle with the cautery, and after cauterizing anew the cut surface leave the stump in the peritoneal cavity without any kind of ligature. Aug. Martin also believes that in certain ovariotomies the stump must be secured above the abdominal wall, and recommends the methods of Hegar, Spencer Wells, and Olshausen.[2]

In speaking of extra-peritoneal treatment of the pedicle S. Pozzi says: "In spite of this, however, this method should still be followed when at the same time that an ovarian cyst is being operated upon a prolapsus or pronounced retroflexion of the uterus has to be combated, a gastro-hysteropexy being thus at the same time obtained." Dr. Paul F. Mundé, in his interesting article on "Surgical Treatment of Retroflexion and Prolapsus of the Uterus," mentions that, according to Kelly, this operation should be called hysterorrhaphy.[3] The attachment of the stump above the abdominal wall is generally effected by means of elastic ligatures, and with two needles skewering it crosswise. The points of these needles are afterward cut, and under each of their ends are placed rolls of iodoform gauze in order to protect the tissues.

Better than the needles already referred to are the pins used by other operators, which are furnished with a kind of head with two flat sides, and with a flat sheath to cover the point after piercing the pedicle. But neither the one nor the other offers sufficient resistance to counteract the tendency of the pedicle to go inward, and they, besides, sometimes wound the skin, while if the pedicle be too far back they hurt the borders of the incision and retard its subsequent healing.

As far back as 1852, E. Martin spoke of extra-peritoneal treatment by means of a screw; in 1858, Hutchinson invented a clamp which was immediately accepted by such eminent men as Spencer Wells, Atlee, Wilde, Koeberle, Hegar, and Kaltenbach. Other operators used Cintract's serre-nœud, and lastly, Clay and Baker Brown invented a cautery-clamp. Although Stilling in Germany, in 1841, and Duffin in England, in 1850, returned to the old method of intra-peritoneal treatment, it did not become general till the year 1880, notwithstanding that it was frequently recommended by Sir Spencer Wells.

The number of these clamps is considerable, and I may venture to state that the majority of gynecologists have got a model of their own made, and some, like Spencer Wells, as many as three. Those of Küchenmeister, Billroth, Atlee, Wilde, T. G. Thomas, Koeberle, Dawson, Lloyd Roberts, Lawson Tait, and some others, are so well known that I need not describe them; I shall simply state that the greater number of them are parallel clamps, but as the pedicle is generally more or less round in form, its tissues are lacerated, while the force with which they are held is unequal in different



Clamp No. 1.

places. Those which grasp the pedicule circularly are the best; but as it has been difficult to obtain this result from the simple use of two rings, other contrivances more or less ingenious have been added which render them very large, heavy, and clumsy. With the exception of Lawson Tait's, I consider them all difficult to be used.

The clamp No. 1, which I have the honor to submit to the notice of gynecologists, is composed of two concentric arcs of circles (Fig. 1), the breaches or interruptions in which are about one-third of their complete circumferences, and these breaches permit of the introduction of pedicles of extraordinary size, notwithstanding the smallness of the instrument. The button D passes through P until the inner arc A closes the circle (Fig. 2); the screw C is then attached, and working by means of the key E, pushes the arc A through the body of the outer arc until the pedicle is subjected to the necessary amount of pressure. The oval piece L stops at the proper time the further passage of the arc A, and prevents the pedicle from protruding between the plates forming the arcs. This simple contrivance is very light in weight, and could be still lighter by being made of aluminium; it is very aseptic, and permits the wound in the abdomen to be easily stitched, by maintaining the

[2] Traité clinique de Maladies des Femmes.
[3] The American Journal of Obstetrics, November, 1891.

pedicle at the proper height, and sufficiently immovable to allow the wound to heal.

Although in ovariotomy it is not usual to treat the pedicle outside of the abdomen, in hysterectomy, on the contrary, very few operators leave the stump inside of the pelvic peritoneal cavity.

The reason of this, in my opinion, is that in ovariotomy the discharge from the pedicle is not very great, and reabsorption is more easily obtained, while in supra-vaginal uterine amputations the discharge is very copious and rapid, and reabsorption is not easily arrived at. The holding of the same, or similar opinions, has doubtless caused A. Martin to adopt the prophylactic system of drainage by means of a cross tube inserted in the cul-de-sac of Douglas, which he leaves in the vagina for three or four days after the operation.[1]

Inter-peritoneal treatment, according to the technique of Schröder, is little used, because it exposes the patients to infection and increases mortality among them.

In most cases of hysterectomy the pedicle is treated by the extra-peritoneal method, as practised in different ways by Hegar, Wölfler, Hacker, Sänger, Bandenheuer, and Kleeberg, of Odessa. These methods have reason on their side and show more favorable results than any others. But no matter what method may be employed, all operators have to use a provisional elastic ligature to prevent hemorrhage during the operation. Such a proceeding is the same as that followed in general surgery in amputation or disarticulation of the extremities.

Both provisional and final ligatures are obtained by knotting the rubber tube with itself, or with thick silk threads, and transfixing or skewering the pedicle with two large pins, in the same manner as in ovariotomy. Some gynecologists have invented forceps and ligateurs, the former serving to hold the ends of the ligatures while being tied with silk thread, and the latter, like those of Pozzi and Segond, to make the tube exercise a permanent constriction. Walcher uses for the same object an agrafe, which with a pincers holds the ends of the ligature.

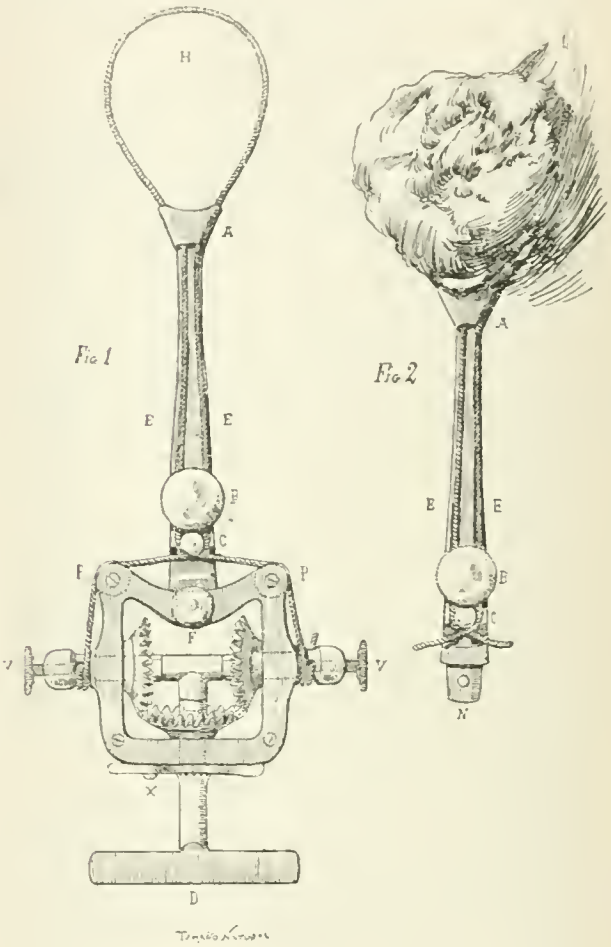
These instruments solely serve to firmly hold the ligatures, and by no means to grasp and hold the pedicle. The different serre-nœuds and constrictors known are not used either, for they are not well adapted for making ligatures of any description.

With my clamp No. 2, these ligatures can be made as rapidly and easily as may be desired. The constriction is effected, no matter how distant and narrow may be the spot where it may be desirable to locate the ligature, and this ligature may be slackened, tightened, or removed afterward as much as may be requisite without hurting the edges of the wound, or touching them too much either with the fingers or the instruments in loosening or cutting the knots. The ligateur also serves first to hold the uterus in an immovable position during the operation, and afterward to hold the permanent ligature by maintaining the pedicle in a proper position and hindering it from returning to the peritoneal cavity.

This clamp is also very useful in the "Ventro-Fixation Method," in which the pedicle, through its shortness or thickness, cannot be made to protrude from the abdomen. In this method Kleeberg, of Odessa, was the first to use the elastic ligature, letting the stump return to its place in the pelvis, and leaving the extremities of the tube in the wound to serve as connections and drains. Péan employs a forceps, which serves to compress the stump and to act as drainers.

In the systems of Wölfler, Hacker, and Sänger—the latter being particularly happy in his modifications of those of Schröder and Hegar—this clamp is of great utility, for it compresses and holds the pedicle in the desired position while producing drainage.

In Fig. 1 the clamp is shown ready for constriction. The pedicle or uterus having been encircled by one or two turns—according to circumstances—of the elastic cord, the loop H is formed, the two ends of the cord pass through the mouth A of the fixateur, follow the direction E E, and passing under the screw B cross each other under the button C, and are rove on the pulleys P P and afterward coiled on the axes V V, which, by means of the handle D, put in motion the three cog-wheels of the inside, and these, being checked by the spring X, cannot by recoiling slacken the hold of the loop H when the hand of the operator is removed from D. When the constriction is effected the ligature is held by turning the screw B, and the fixateur is disattached from the clamp by giving a contrary turn to the the screw F. The opening A remains in close proximity to the stump (Fig. 2) and the



Clamp No. 2.

cords E E, held by the screw B at the button C. The end N is that which is attached to the clamp. The length of the ligature may be from two centimetres upward, according to the requirements of the operation.

As will be seen, this instrument serves as constrictor and ligateur of the pedicle, and allows of the use of various ligatures if sufficient ligateurs are to be had. In the vaginal treatment of some fibroids and polypi it is of great service, and the rubber cord can be changed for a wire or écraseur, thus allowing the section to be made without difficulty.

I have had made some ligatures of fine, soft, galvanized wire, which are seen in the diagrams, from which wire very flexible cords are fashioned, which, though sufficiently thick to be inserted into distant parts of the womb, are much more ductile and strong than any other class of wire employed. In like manner it can be used for the galvanic loop, by employing a wire with an insulating substance, and being provided with a hard-rubber ligateur.

From the simplicity of the mechanism of its *fixatem* it is thoroughly aseptic, while being very easily cleaned, and is particularly adapted for those operations in which it is at the same time necessary to firmly grasp the stump and to hold it in an immovable position.

REMARKS ON FUNCTIONAL PARALYSES.[1]

By A. PESKIND, M.D.,

PROFESSOR OF PATHOLOGY MEDICAL DEPARTMENT UNIVERSITY OF WOOSTER; VISITING PHYSICIAN TO THE CLEVELAND CITY HOSPITAL, CLEVELAND, O.

As three very peculiar cases, characterized by functional paralyses, have occurred to me within the last two months, I beg to offer their report, giving the reasons which guided me to class these cases under the category of functional paralyses.

CASE I.—Mrs. V——, aged thirty-three, was admitted to the City Hospital as a paralytic, a result of cerebral apoplexy, which occurred a week previous. This was the only history obtainable from those who brought her there.

On admission Mrs. V—— represented a true picture of the stated affection. Left hemiplegia, right facial paralysis, aphasia, complete aphonia with deviation of the tongue to the paralyzed side, were all well pronounced. The patient could see and hear everything; the eyes were normal to all appearance, but no sound could be produced by the patient. The physiognomy of the patient was highly expressive of that morbid mystery known as hysteria. This physiognomy and the total aphonia urged me to look more into the case. The reflexes of the paralyzed leg were first examined, and here a striking peculiarity was observed. The patient was at first told to bend her knee. Of course she could not do it. On tickling the sole of the foot the paralyzed leg would draw up nearly at right angles to the bed, and then it would resume, slowly or quickly, its former position, irrespective of the amount of the irritation employed. On placing the leg so that the heel touched the sacrum the patient would voluntarily extend her leg. The suspicion thus having increased, I contemplated another test. I addressed myself to the resident physician, who accompanied me, and directed my eyes so that the patient was still within the field of my vision, although I appeared to look at a remote object. I spoke of the condition of the patient, about her age, which renders the case so much more serious and deserving due consideration. That prompt and active measures are imperatively needed to bring about the prompt cure, which is the only chance to obviate her becoming a helpless cripple. Mrs. V—— listened to my sympathetic remarks with absorbing attention, so that the wrinkled brow was smoothed and every vestige of paralytic distortion vanished. I stopped and all went back as it was, visibly to all those present. My patient needed encouragement and I promised her that she should talk next morning. Two grains of quinine and $\frac{1}{60}$ of a grain of strychnine were ordered to be given, dry on the tongue, every two or three hours. At my next morning's visit my patient obeyed my orders. She answered distinctly, though with a thick tongue, every question I put to her. I then took her arm and commenced to promenade the spacious ward. At first Mrs. V—— dragged her limb as if it was a dead mass; soon, however, the leg was drawn up a little, and when I increased my speed the patient began to limp on the sound leg, keeping the paralyzed one flexed. From that day on Mrs. V—— was ordered to walk about, supported by a chair. So she did. Again and again have I noticed, to which I have called the attention of the attendants, the drawn features disappear when the patient was not aware that she was noticed. I had no chance to watch her during sleep. At the expiration of ten days after admission I obtained a battery for the hospital and brought it to try on Mrs. V——. Even before I opened the battery Mrs. V——, all at once, turned perfectly blue, a clammy sweat covered her whole body, so that I was alarmed at her appearance. I tried to quiet her, and after some time I applied the battery for a few minutes. The reflexes were all normal. Next morning Mrs. V—— said she felt better, and requested her discharge from the hospital. This of course was granted her. She walked, guided by an inmate of the hospital, to the street-car, and again from the car to her residence, a distance of several hundred feet, while about ten days before she was entirely helpless. I subsequently learned that Mrs. V—— was not doing well, so I went to see her. She was worse, indeed. Both legs were œdematous, her movements were much weaker than when she left us. She said the nurses looked upon her as a cheat, and she did not like a city hospital. I inquired at the same time of the friends about Mrs. V——'s former state of health, and I learned that she always was very nervous, and went to doctors. I visited her last attending physician who treated her before the paralytic stroke. The doctor said that the patient suffered from tachycardia, congestion of the liver, and œdema of the legs. The treatment consisted of blue mass, iron, quinine, and digitalis. The nervous element was the most troublesome in the case. There was no organic lesion of the heart. With such premises what must be the conclusion? I, for my part, diagnosed this case as one of functional paralyses, notwithstanding the existence of a facial paralysis. My time is, I am afraid, too much spent on this case, as I wish to report two more cases.

CASE II.—Mrs. L—— came to consult me about an amblyopia of about six months' duration. This was the history, given August 8th:

About seven months ago Mrs. L—— had metrorrhagia, which lasted about six weeks. She had always been regular prior to that for a period of two years, when her youngest child was weaned, and it was the first time such a flowing ever happened to her. Mrs. L—— did not know whether the metrorrhagia was caused by an abortion or not Her physician, she said, did not think so. When the hemorrhage was diminishing a fever developed. At this time a left facial paralysis made its appearance, with aphasia, amblyopia, and paralysis of the tongue on the left side, the tongue deviating laterally left on protrusion. These phenomena, excepting the amblyopia, disappeared in a few days. About six weeks after the facial paralysis passed off a right brachial monoplegia appeared. This trouble required six weeks of treatment to leave her. On examination I have noticed some queer conditions about this case. She complained of bitemporal hemianopsia, with indistinct central vision; at times the patient could see, but could not locate things. The ophthalmoscope revealed a pale disc, with no other structural changes. There was no disturbance of color perception. The patient was then directed to look at a certain spot, with my open hands spread before her eyes. She saw something. I closed my hand, she still thought that she saw something, perhaps the hand, but she did not know where it was. I opened the index-finger, she saw the index-finger. The middle finger was opened, she saw two. On opening also the ring finger, the index-finger alone was seen, but not the other two. When I placed the middle finger in place of the index, the middle finger became invisible; the thumb, however, placed where the index was seen, was visible. I requested the patient to write my name; she dotted the "i" on the right place, though she never wrote my name before. So she dotted correctly every "i" of such words as emancipation, etc. When I called her attention to this, and dictated her to write, "The committee recommended to introduce cordiality," the change in writing was conspicuous. The method of directing her writing is extremely peculiar as the paper shows it. I shall not repeat all the devices used to confuse her, but I was convinced that Mrs. L—— saw more and better than she would have us know. Again, she could not see an object placed within the field of vision on the temporal side, when the object was near the temporal side of the eye. The same object, however, she thought she saw when it was at the, probably, extreme limit of her field of vision on the temporal side, when I first remarked that "I thought she had a far-sighted eye," and carried the object farther away. The cutaneous sen-

[1] Read before the Cuyahoga County Medical Society, Thursday, October 1, 1891.

sibility was tested. The two points of the æsthesiometer were passed through the skin of her forearm, and she only felt one single slight pricking, though the points were over three inches apart. The same two points on the left side of the tongue felt like two points, while they felt like three on the right side. The diagnosis was made, and I promised a cure to my patient as far as eyesight was concerned.

I subsequently wrote to her family physician out West, whence the patient had come to be treated for her trouble, and the doctor was very kind indeed to answer me promptly about the case. An abstract of the letter, verbally, tells us that "Mrs. L——, aged thirty-two, had been treated by another physician for seventeen days for a profuse metrorrhagia" (when the writer was called, and) "in four days succeeded in stopping the hemorrhage." At the next menstrual period a fresh metrorrhagia appeared, which finally stopped "after fourteen or fifteen days of the use of tampons, styptics," &c. Mrs. L—— "was left utterly prostrated and almost exsanguinated. Slow, low fever sprang up, and one morning I found her with almost complete facial paralysis on left side. Tongue was completely beyond control and seemed very thick. Eyes were staring and mouth drawn. . . ." Gradually these symptoms improved, "but eyes never became normal. . . ." Then, "one day, while sitting on her porch, she felt that she could not use her right arm. . . . Her mind has been much affected. . . . Extremely nervous, low-spirited, giving way to tears easily. . . ."

I omitted to state that on examination of the generative organs a diffuse pelvic cellulitis, with a fixed, retroflexed uterus, with a gaping os were detected, and probably explain the character of the low fever the patient suffered from at the beginning of her present ailment.

Let us reason about the pathological coincidences in this case. We have here a case of paralysis of a queerly crossed kind. Left facial palsy with aphasia—something very unusual. An amblyopia also of a peculiar manifestation. Then follows a monoplegia. Where is the seat of lesion? These disseminated lesions could not be due to basic affections of gross character; neither atheroma of the circle of Willis nor a basic growth could be admitted in this case with such a sudden onset. Pressure from effusion is not plausible, because more nerves would have been involved than the optic (or corpora quadrigemina) with the facial; nor would the optic disturbances have lasted longer than the facial paralysis. Subsequently a brachial monoplegia develops, which contends against such a supposition. Was all this due to a cortical lesion? This does not seem to be probable; the lesions would be too diffuse and affecting now the frontal and occipital lobes together. The one is cured in a few days, the other remains unameliorated for months. Then again appears a brachial monoplegia—a frontal lesion again. An intra nuclear disturbance does not explain the symptoms. Of course the vascular system may be the seat of trouble, but this cannot be of gross structural alterations. Then let us analyze the history of the case.

We have here a patient "whose mind has been much affected, . . . extremely nervous, . . . giving way to tears easily;" a lady, who can cry whenever she deems it necessary or desirable; a lady who is social, loves fashionable literature, one who needs doctors, numbers of them, to stop her metrorrhagia; a lady comparatively young, anæsthetic, hyperæsthetic, is feverish, has a pelvic cellulitis, and the fever is of a low type; is stricken with a left facial paralysis, which disappears soon, then an arm becomes involved which requires six weeks to get well, which, however, does not disfigure the face like the facial paralysis did. Now, all this is nothing compared with loss of sight, though no one can see that the patient cannot see, though she may see. The diagnosis was made. My prognosis was given as extremely favorable, in spite of the patient's deep despair.

A word as to the treatment of this case. What was left for me to contend with was to restore sight to eyes that could see, and build up a run-down system. While the general treatment was the most important, the restoration of the eyesight was the hardest task. The patient was ordered to bed for a week, so as to give her rest as much as possible. Blistering plasters were applied behind the ears, and the eyes ordered to be kept closed. Internally Parrish's chemical food, tinct. strophanthus, and one-thirtieth grain of strychnine sulphate were given. The patient was getting better. At the end of the week the patient was ordered to walk up to my office, a distance of several hundred feet, all riding was forbidden. The general improvement became soon apparent, though vision was still imperfect. One day while talking to the patient she made a remark that she feels her jaw becoming paralyzed, and she began moving it as if the jaw would be dislocated. By a little manipulating the jaw was all right up again.

Central galvanization was also used, and sudden interruptions of the current produced mild shocks, which appeared to have a favorable influence. The patient was also told that if such treatment be ineffective, I should have to apply something over her temples, which would leave a very slight disfiguration. To this my patient objected as a woman can: "Doctor, I will not let you mar my beauty," was the reply, in a voice which betrayed both the hypocrite and the humorist. "Heaven knows that I am trying my best not to need to have recourse to such means," was my earnest response.

N.B.—The patient's eyesight is much improved. She copies now from printed matter in small type without any mistakes. Her pelvic trouble is still great, though nothing special has been done for it, as the environments where the patient stops are not favorable for the treatment.

Case III.—Miss B—— was admitted to the City Hospital January 11, 1882. Her history of that date read: Age, thirty-seven; nativity, Ireland; housewife. The cause of her admission is recorded that she was "sick." In the Medical Record of October 21, 1889, the diagnosis is stated to be made: "Chronic rheumatism and spinal disease." Her present history, taken August 3d, reads:

Miss B——, aged forty-three; nativity, Ireland; by her former occupation a cook; single; menopause for some time past. Up to fourteen years ago her health was very good; no previous sickness. Fourteen years ago she slipped on an icy sidewalk, fell striking her back on a post. For nine following years her pains grew worse. Four years ago the paralysis of the lower limbs, followed by paralysis of the right arm and a hunch of the right side of the chest rendered the patient bedridden. No urinary nor bowel trouble ever happened beyond a slight constipation. She would not eat any solid food, though she has a fair appetite, but subsists on a diet consisting of milk, beef-tea, eggnog, etc. She thought some time ago that the bed was not soft enough, and the kind nurse provided for her an air bed.

Miss B——, an invalid for many years, is still well preserved. Her face is full, and she is quite corpulent. Both lower limbs are helplessly stretched, with muscles in extreme contracture, so as to throw the feet in an equino-valgus position. There is a lateral deviation of the spine, and the right side of the chest is so deformed that the whole of the thoracic viscera seem as if incarcerated in that side of the chest, the bulging of which just fills up the triangular space formed by the bedding and the patient's body. The right arm is paralyzed with contracture of the muscles of the fingers and wrist. No visceral lesions are detectable. While Miss B——'s limbs are extremely stretched in bed, when she is placed on a stool they drop, bending at the knee as if by their own weight.

The appearance of the woman, her peculiar position in bed, the dropping of the legs while sitting on a chair, urged a closer inquiry in the case regardless of the recorded diagnosis. No battery was at hand at first, so I

had to be satisfied with the examination of the reflexes. No knee reflex was obtainable, as the muscular resistance was too great. There was a very marked ankle clonus, especially of the right leg. It is through tickling and pinching the soles of the feet that my suspicions became more corroborated. These peripheral irritations have thwarted all her resistances. On successive and repeated irritations, the flexings of the legs and their extensions followed so quickly that it became amusing to see the patient kick whenever she thought that she was going to be pricked. Frequently she would draw up her legs and hold them in this position to avoid the pricking. I told her, however, beforehand, that the instrument I used would cause such reactions, so as not to let her think that I wished to detect fraud by it. The instrument I used was nothing else than a nail-file. This all went to prove that Miss B—— could do more than she would. I then forcibly flexed the leg on the thigh. The leg would straighten at once as soon as I let my hands off. Doing the same, but holding the leg for a few minutes and speaking attentively to the attendants, or asking the patient some questions, the leg would remain flexed for many minutes after I took my hands away.

My diagnosis was that we have a case of functional paresis, the result of weakening of the ligaments from overstretching them by contractures of years' standing.

Let us analyze this case. We have here a woman who fell some fourteen years ago. Five years subsequently she comes to the city infirmary "sick;" there her sick spells were getting worse and the limbs began to give way. Nine years after the slight trauma she is a bedridden paralytic. Is there a progressive spinal lesion of such long duration and such large extent, with so little disturbances of nutritive processes? Are these phenomena and the result obtained through examination consistent with any distinct lesion generally designated as organic? Massage and a little rough handling free the contractures a little in one day. In a few days improvement was marked. Assisted by my friend Dr. Crile, in the presence of Dr. Straight and the resident physicians, an anæsthetic was administered to Miss B——. Every distortion of the body vanished. Before the patient regained complete consciousness the knee reflexes were tried and responded normally. In the meantime the nurses told the patient what I thought about her case, and I felt it one morning. This was my best lesson of woman's wrath. I considered myself much safer to see her paralyzed, and my prophecy about the future of Miss B—— not yet realized.

About the ankle clonus in this case, I think it was due to the extremely powerful resistance of the muscles of the legs and relaxation of the ligaments.

I hereby show you the photographs taken with a detective camera, after my opinion had been disclosed to the patient. The improvement in the position of the fingers is shown, which were in extreme contracture before. The rest speaks for itself.

Thus I have revealed my reasons for the diagnosis made in the three cited cases, characterized by a peculiar loss of muscular mobility. What, may one ask, do we understand by a functional paralysis? I, for my part, always consider a functional disturbance of any kind the result or results of material changes brought about in certain structures, which changes, undoubtedly molecular, are too minute for our direct observation and physical investigation, but which are conceivable and have deductively a plausible existence. In other words, the difference between an organic, properly so called, and a functional affection seems to be more of quantity, the quality depending on the peculiar site of the lesion or area involved. Therefore by a functional paralysis such a one is considered where the abolishment of muscular function is caused by changes, probably in the nervous system, which changes are mechanically invisible. To concede that such changes are possible we need only reflect on the power of matter in its most attenuated state. When worlds can appear as a mere *inanimate* speck on the background of the photographer's camera, and this scarcely visible speck still represents every depression and elevation of the immense worlds, shades and lights are shown. The memory is so much like a photographic impression that the simile between the two still more strengthens the supposition of its material existence. When everything is favorable—the proper subject, the exact light, the correct focus, and the camera in good working order—a picture is obtained which properly represents the real in a state of rest.

When the subject is unstable, the impression is unstable and the image is confused, often beyond recognition. So with memory. When all coincidences are favorable, the mental state is clear, and the subject is a proper one, a mental image or impression is obtained which can be reprinted or recalled from the labyrinth of the nervous edifice. These memorizable impressions need a place having dimensions. When the mind is preoccupied with other ideas, or the subject is not sufficiently stable, the resultant image is confusion—nothing to be made out of it, all memory is lost. This is why the insane remembers things that happened to him before his alienated state, recalls impressions of long past events with, at times, astonishing vividness, while occurrences of to-day find no place in his memory, either on account of the instability of the presenting subject and lack of the proper attention—the time needed for the impression to be formed; or there is a dark subject shading the focus, and covers with a fog of forgetfulness all things. It is not my object to speculate about the seat of mind, but, were the powers of matter known, we would have more of the wonderful and less of the miraculous, and many so-called functional disturbances would have—I hope, will have, in a near future—a more comprehensive meaning and science would take up their course.

Well, then, where is the seat of lesion? A pertinent question. I do not blush to admit my ignorance, I am not ashamed to say that I have not mastered the functions of the nervous system to that extent. I have, however, done something on this subject, and I shall take the liberty to divulge my speculations. It would seem that in the great majority of these cases in which the functional disturbances are such as to appear beyond the control of the individual, that these disturbances are in the conducting paths of the various parts of the nervous system, the function of which is to produce effects designated as mental actions It is through the disturbances of these paths that these perversions arise through them. Conscious impressions are deflected from the seat of the will; unconscious impressions are conveyed to the seat of consciousness; usual involuntary actions become voluntary. That even these mental states must have representative seats in our nervous system we infer from this very fact, that some neurotics can cause, by their unconscious wills, to appear involuntary phenomena. Of course these paths are not the only ones always affected. In some cases other areas are involved, while in still others there seem to spring up morbid changes, manifesting themselves by peculiar irritabilities, as the result of practice of vicious habits, or irritating some special spot either consciously or unconsciously, which result in special lesions with the production of special functional perturbations. That this trouble must be in the nervous system, and probably a result of some local perversions of nutrition, seems beyond doubt. The manifestations of the effects of such perversions is what we meet in practice. The motor disturbances are too well known. The sensory perversions are characteristic of this affection. The suddenly benumbed foot, that the patient is afraid to move for fear she will fall, not feeling her steps; the dead arm, the startling back, the splitting headache, are all too common complaints. The sympathetic nervous system is almost always involved, and, perhaps, through its influences on the nutritive processes the sensory organs become implicated. Through it we have often to encounter most alarming and dreadful scenes. Through

it the ovaries swell, the lungs bleed, the heart throbs, the stomach bloats, the legs swell, the tongue becomes thick, so that it chokes the patient. Through it the pale face, the cold sweat, and the hot chill.

The so-called neurotics are most frequently affected by these functional disturbances. The grand type, which cannot be classed among the impostors, are, as a rule, hereditary neurotics, and the least irritation is sufficient to shatter their nervous stability, to affect their nutritive processes, and thereby still more add injury to the mischief. From early childhood can be traced its development. Exquisitely false presentations, abnormal wills, perverted consciousness, are common to all these cases, even in apparent health. All debilitating influences and disordered general nutrition, prolonged peripheral irritations, will excite perturbations and interrupt the harmony in nervous action. The latter conditions are the chief causal factors in cases where the neuroses are acquired. Vicious habits, as said above, have much to do with its development. The difference between the hereditary neurotic and the one who has acquired it is extremely great. In the latter class will and consciousness are seldom if ever affected.

The three cited cases illustrate much of what has been said, and, undoubtedly, every other case would show some other point of departure from normal nerve-action. Both the first and second cases are high-strung neuroties from their birth, if not prior to that. Mrs. V—— represents the highest type of mental perversion, manifested by disturbances of function. Mrs. L—— was of a mixed type. She made a good deal of all for the sake of making them so. Much, however, has been done unconsciously, as if on suggestions, and was probably due to hereditary vice, and peripheral irritations from the pelvic viscera. It is Miss B——'s case which illustrates a type of conscious aberration from healthy nervous action, with the production, voluntarily, of functional perturbation, which may remain permanent as a result of secondary changes in the nervous system. Miss B——, a maiden, past her second sweet sixteen, worries about her burdensome life, broods over her future, how to avoid the *ennui* of the coming time, when the summer of life has fled. As a cook her tastes, perhaps, become ancient, the younger will displace her. She would and wished better to be crippled and bedridden than alone and forsaken in the world. To get that way is not an easy task. Time, however, has wrought greater wonders. A slight trauma is sufficiently suggestive. The paralysis develops gradually from voluntary contractures of the muscles and subsequent relaxation of the ligaments, which has also caused the hunch. With such a hypothesis of the pathology of these neuroses, what would one offer as a prognostic promise?

To be able to make a prognosis in any disease one must be well acquainted with the nature of the malady, its pathology must be thoroughly understood, the symptoms mastered, the knowledge of the cause, and the duration acquired by experience, observation, or study, as well as the effects of treatment on the disease. These are the reasons why a positive prognosis is so difficult to state in these cases—these neuroses being so varied in kind, with so many differences in their pathological manifestations, that broad prognostic rules are impossible. This, though, can be said, that the majority of the cases get well through proper care, especially so when all exciting causes are removable. Some, however, with the best of management and with the greatest trials, are only ameliorated, and relapses are too frequent. Still others, in spite of all efforts, grow from bad to worse, and fall victims to the disease; nevertheless post mortem no special pathological change may be demonstrable. It would seem that the cases which are characterized by functional disturbances, unconsciously produced, have a better chance than the cases with conscious volitional perversions. While in the first proper and steady management will bring about a progressive amelioration, with the latter class the will has to be brought to subjugation by strange stratagems to overcome the resistance of the patient. The too frequent relapses, however, render the prognosis in the majority of cases very gloomy.

When all I knew of disease and its treatment was the dictum of the text book, nothing seemed as trifling to combat as the functional neuroses, of which hysteria is an illustrating type. Why, the devil's tincture and everything offensive to olfactus would be a panacea. Antispasmodics and narcotics are the chief remedies. In fact, a great many look upon these neuroses with airs of satirical lightness. Unfortunately, however, for the practitioner, as well as for the patient, the neurotics are hard cases to handle, much harder than I ever anticipated before I came in contact with them. Very often the patient with the vapors possesses high intelligence, is of a refined character, too often really a pitiful creature and a great sufferer, even by her own self-wrought tortures. Although very often it is a mere "comedy, for there is nothing of a very serious or gloomy character in all these events," as the illustrious Charcot tells us, this great man also hints of some cases which terminated fatally, and which do terminate so every day. I think nothing is so trying as to treat a serious form of these neuroses. Not only on account of the severity of the disease, as of the circumstances so often complicating it. Indeed, what is the method of treatment of such cases? What is the object one aims at when he wants to cure such a case? The normal transmission of impressions, re-establishment of healthy nerve-action, restoration of general health, and to produce regeneration of wasted or altered nerve-tissue, are all required. In other words, the mental and corporeal aberrations must be attended to. This is why success is not always obtained by the usual method of treatment. Many neurologists have hinted at, and even insisted on, the value of training these cases to normal nerve-action. It is through the attacking of the effect that the offending cause can be expected to be removed. It seems that to win success in the treatment of these cases one must be a psychologist. Physiological psychology must be his guide—a psychology which is not only scientifically stuffed with speculative suggestions, having no real representation in the actual universe, but one based on practice and experience. To master this is synonymous with mastering of the mind, something apparently impossible. Much, however, can be picked up by observation and study to utilize for the relief of these sufferers and keep them doing well, if we cannot cure them. The symptoms must be studied carefully and the points of aberration noted, watched, and adroitly attacked. The diverse perversions of mental action must be studied in every case. The most essential part is, however, to gain the patient's confidence, which is easily obtained when one knows what he has to do. If the patient will try to frustrate all efforts for the mere sake of spite, the task becomes an extremely difficult one, almost insurmountable. Even abominable mysticism has at times to be resorted to, especially in those cases where the disclosure of the truth would be an insult, if not a death blow to all efforts. To tell a lady that she is not paralyzed when her limbs are dead like a mountain, or to tell her that she can see when she assures you of her blindness, is much worse than an insult; it is equal to calling her an impostor, and it means you do not understand her—you cannot cure her. Regardless of cold-blooded ethics, to be successful it is unavoidable to admit the awfulness of those dire, dreadful, deadly, inexpressible, fulminating, stormy, suffocating, startling, smothering sensations, but they must be curable. Doubt does not go in these cases. One must be sure. Nor is there wisdom in the teaching of self-possession, self-control, or in the urging of not doing this and avoiding that. Let the feelings be expressed. When she feels like crying, tell her to scream, the louder the better. When the muscles twitch, let them go—no holding back. The more an enemy is shunned the oftener he is met, proves very often to be a useful hint. All this leads to victory in the majority of cases. In the same time steadily, persever-

ingly, persistently, even insistingly, timely and opportune, habituate the patient to confront and to tolerate the presence of the object she abhorred, and to do what she thinks she cannot do. All silently but intentively. It is in these cases where often the best kindness is severity, but the severity must be kindness. As a physician, one must know how to be true to his cause, even when degrading himself for a while in ugly mysticism. Let it be the physician's touch, his words, his suggestions, his drugs have accomplished everything; it is the patient who must do the work, although unaware of it. It is a severe struggle, and the reward is too often insignificant, if at all. Then one must fight against numbers of obstacles. Sympathetic friends and officious nurses are the most conspicuous, often the removal of their influence is sufficient to cure the patient. This, however, is not always possible, and the method of treatment becomes so much more complicated and difficult.

The hygienic treatment is of extreme importance. In this class of neurotics rest in bed is to increase the patient's infirmities, but over-exertion is perilous. Attention to cutaneous activity is of extreme importance. Baths, followed by thorough friction, do much good. Out-door life, even if this be sitting on the porch, is better than the bed. The rocking-chair is a good piece of furniture if the carriage cannot be obtained or the patient's state of health prevents its use. Something to do manually and mentally is invigorating, and knowing the patient's tastes and abilities, this can easily be accomplished. The diet must be nourishing, and often the patient will consume more on a fly than at the table, and opportunities must be provided that she may get something nourishing anytime and just handy. Medicinal agents have also their place, and are too frequently much needed. We have here to restore the tone of a depraved nervous system, and, as a rule, general malnutrition. While in the mild forms of these neuroses, characterized by congestive phenomena of the internal viscera, the bromides, chloral, valerianates, and similar drugs are extremely useful to tide over the critical moments, for such are the whole manifestations of the disease; in the form of neuroses under consideration these drugs are worse than useless as far as their curative power is concerned. If the patient complains of restlessness, and restless are they always, with nervous feelings, the best calmative medicine is giving nothing. This, however, cannot be carried out too rigidly. Friends have something to say. The erethism may be so great as to lead to exhaustion, then something has to be given to quiet the patient. I think there is no drug as useful as alcohol administered in the form of medicinal tinctures or malt. Compound tincture of cardamom has done me good service. Occasionally a dose of chloralamid may be dissolved in the alcoholic medicine and will aid much to procure rest. Of course great care is necessary in the administration of any form of alcohol; the nervous temperament of the patient, the chronicity of the disease, require thoughtful consideration, and a habit may easily be acquired which would be worse than the disease itself. This, however, can be obviated very easily. Some encouraging and discouraging remarks will help the patient to leave off the quieting medicine. Habits are generally acquired through the fact that there is a knowledge that a certain thing is the thing which can relieve the desire or distress.

It is the restorative medicines one must rely upon, agents which are not depressants, but exaltants of cellular activity. Strychnine, caffein, quinine, iron, are the most useful drugs. They are not only the curative agents, but they are preventives of the most dreaded relapse.

Old Folks in Japan.—In a population of about 40,500,000 in Japan there were, in 1890, 81 persons of 100 years of age, 46 of 101, 26 of 102, 7 of 103, 6 of 104, 1 of 105, 7 of 106, and 3 of 107; in all 177 persons of 100 years of age or older.

AN EXTRAORDINARY EFFORT OF NATURE TO RELIEVE AN INTUSSUSCEPTION.

By EVERETT M. CULVER, M.D.,

NEW YORK.

Dr. Weir's article in the Medical Record of February 13, 1892, "Remarks on Subdiaphragmatic and Rectal Abscesses of Appendical Origin," brings to mind the following remarkable case of the course of an intussusception, which must be instructive to both physicians and surgeons, as the case simulated typhoid fever in some respects, and illustrates how pus may reach up to the under surface of the liver and down to the rectum from the right iliac fossa. As the original disturbance occurred in the appendical region, and is identical in some of the results to Dr. Weir's case, I have amplified the notes, which I have had in my drawer for the past two years.

Ordinary cases of intussusception are not so rare as to be made the subject of journal articles. Had the course of the case reported below been of the usual termination—either of spontaneous cure or operation—there would have been felt some hesitancy in presenting the same without an excuse. The effort taken by nature in this case to relieve an obstruction of the intestine was truly remarkable. If the autopsy of the subject had not been witnessed and vouched for by eight of the writer's colleagues, your reporter would have hesitated in printing, without such confirmation, the statements following in relation thereto. The late patient, whose malady is the subject of this article, was accompanied to the Manhattan General Hospital by his mother (a nurse), who gave the following succinct history, which is abbreviated from the hospital history-book as follows:

Frank M——, aged twenty-one, United States, single; admission October 10, 1889, at 5.30 P.M. While at work was suddenly attacked with cramp-like pains in his abdomen, so severe as to necessitate his leaving his employment. Returning to his home he went to bed, he became steadily worse; and after some days a physician was called who found him vomiting at intervals a greenish fluid. There was some elevation of temperature. At this time there was distinct dulness on percussion over the right iliac fossa, an ill-defined tumor on palpation, also pain and tenderness in that region; bowels constipated. This physician made the diagnosis of a perityphlitic abscess. (An experienced surgeon would have considered the above signs as good evidence of intussusception).

A few days later the abdomen began to swell, and became tympanitic; this continued until it was greatly distended, there was not much tenderness, and but little vomiting—still constipated, temperature a little elevated. Another physician was then called, who declared that the patient had typhoid fever, and administered a purge (?) which caused diarrhœa. Continued to take nourishment—had free movements of bowels, but gradually grew worse. It was then decided to send him to the hospital, where he came in the ambulance.

Examination showed the patient to be very much emaciated and semi-delirious. There was a history from friends of three weeks' sickness as detailed above; tongue dry and brown; pulse dicrotic, 128; temperature, $101\frac{8}{10}$; respiration, 44. There were no physical signs in the chest; the abdomen was retracted, but there was apparently no pain on pressure; spleen and liver dulness was normal, urine normal, speech rambling and incoherent; no diagnosis made.

October 11th.—Fæcal evacuations very soft, of a dark yellow color, very offensive, not accompanied by pain.

October 13th.—The tongue is more moist, takes liquid nourishment, surface blue, extremities cold, pulse very feeble. Mind sluggish and wandering; hands upheld and grasps at invisible objects.

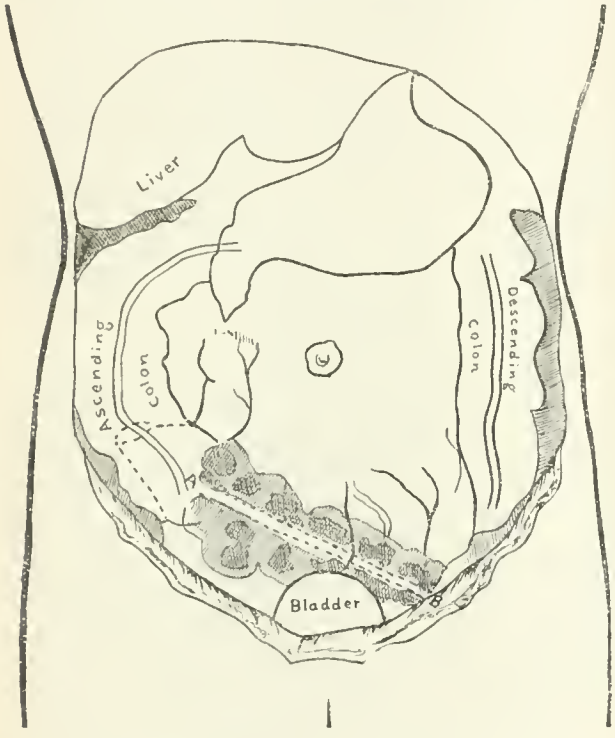
October 15th.—No marked change, pulse more feeble, mind less active, bowels and bladder evacuated involuntarily for past two days.

October 18th.—Became steadily worse, and at 7 A.M. died.

Autopsy—ten hours after death.

Body much emaciated; tongue dry and brown; abdomen retracted. Rigor mortis not marked. On cutting muscles and reflecting same over chest they appeared very dry, dark red, and firm, such as are found in typhoid cases. When the breast-piece was removed the pericardium presented the following remarkable appearance: The whole structure appeared dry, crackling, and so thin as to be transparent, resembling a piece of thin oiled paper. All of the surface markings of the vessels of the heart could be plainly seen through it. The blade of a scalpel was introduced under the anterior surface and the name of the instrument-maker could be read through this membrane. No pericardial fluid and no traces of inflammation.

Heart-muscles dry and red; otherwise apparently normal. Lungs normal; no adhesions; no œdema; they



are bright and glistening, and are filled with air. No signs of hypostatic œdema. Abdomen, no signs of peritonitis on abdominal parietes. The ascending, descending, and transverse portions of the colon were in normal position, only moderately distended with gas. The major part of the small intestine was pinkish, thick, and sodden, contained no gas, and allowed the abdominal wall to sink in. The disease which had destroyed life was then made apparent. The cæcum was in its normal position, but greatly thickened, soft, flabby, and surmounted by a loop of intestine (probably ileum), which was collapsed, and held by a few stringy fibres of soft, new, lymph tissue.

The lower portion of the abdomen contained the interesting features which hereafter claim attention. A dark gangrenous and pultaceous mass spread about a hand's-breath from the right iliac fossa on the one side to the left iliac fossa on the other side, passing and closely connected to the posterior wall of the bladder, and then dipping down into the region of the rectum.

As is customary, the operator first attempted to remove the small intestine by cutting the mesentery between the gut and its attachment to the posterior abdominal walls. When the mesentery was stretched it was seen to be elongated and partly gangrenous about its upper margin, *i.e.*, at the level of the second lumbar vertebra on the left side. The colon on the right side (ascending portion) was therefore raised to sever the mesocolon in order to remove the gut. It was now seen that this portion of the colon, from the cæcum upward about five inches, was thickened, partly gangrenous, and evidently held a loop of intestine, being the sheath of an intussusception from the small intestine passing through the ileo cæcal valve into the colon. When the mesocolon was divided pus escaped from between its folds, and it was seen that the appendix vermiformis was between the two layers of the meso-colon and had suppurated, the pus burrowing up to the under surface of the liver. The pus in this region was of a bright yellow color, and had made its way upward through the meshes of loose connective tissue that binds the colon by means of its mesocolon to the planes of the pelvic and posterior abdominal fasciæ — this singular situation having been gained by the pus while the patient was in bed. The pus found in other portions of the abdomen was of dark chocolate color, more resembling that from an hepatic abscess. This yellow line of pus reached up as high as the level of the pancreas, and must have burrowed in this region while the patient was in the recumbent position. The remainder of the colon to the middle of the rectum was absolutely empty, containing no fæces and but little moisture. From right to left across the lower part of the abdomen the following was recorded:

Several loops of intestine were somewhat matted together by sticky, new, connective-tissue bands, involving portions of the jejunum and ileum, the contiguous sides being firmly bound together; the whole mass being held in place by soft, new adhesions to the fascia of the pelvis, the ligaments of the bladder, and to the posterior wall of that organ, also to the middle and lower third of the rectum. Great care was required in dissecting out this soft, gangrenous, and stinking mass, but after a time it was accomplished, and the portion so removed was found to consist of the first four inches of the ascending colon and its contents, *i.e.*, an intussusception from the ileum; portions of the small intestine, judged to be the jejunum and ileum; the posterior wall of the bladder, and the middle and lower third of the rectum. On cutting open the colon and its contents there was seen to be an intussusception of the ileum through the valve of Bauhin into the colon, the three thicknesses of the gut firmly adherent and somewhat gangrenous. In the pouch of the cæcum, on its internal lateral surface between the valve and the appendix, was an opening which connected with a piece of adjoining small intestine, the two matted together by adhesions, making a passage from that portion of the ileum which entered the colon by the valve, and which had sloughed off on the lower side of the neck of the intussusception inside of the colon, thus allowing the contents of the gut to flow by the strangulated portion of the intestine into the pouch of the cæcum, and on again into the adherent loop of gut; both the wall of the pouch of the cæcum and the adherent gut having sloughed and ruptured at their contiguous points of contact. An adjacent loop of intestine toward the left had likewise become adherent and had become gangrenous at the point of contact, and this continued with each successive loop until a complete passage for feculent and gangrenous matter had been found, emptying into the middle and lower third of the rectum, so that the contents of the stomach, when expelled into the small intestine, found passage through the small intestine alone, completely avoiding the usual passage by way of the entire length of the colon. This new tract was very plainly seen, and was filled with shreds of gangrenous intestine, pus, and fæcal matter. In dissecting it out from the abdomen it was necessary to include the posterior wall of the bladder. That viscera was otherwise apparently intact, and was nearly filled with pale, clear urine. The pelvic fascia was clear, smooth, and glistening. No caries of the pelvic bones was noted, and there was no evidence of peritonitis on the abdominal parietes. The other organs in the abdominal cavity were normal. The kidneys were of good size and color, with no observable (gross) lesion.

What is most remarkable is the entire freedom from peritonitis, since the abdomen contained such a mass of gangrenous sloughing tissues and large quantities of very foul-smelling pus inside the fecal passage. Why no diagnosis was made while the man was in the hospital. I am at no loss to explain, since a brief extract from Mr. Treve's book on "Intestinal Obstruction," one of the greatest authorities, will best serve to illustrate these curious cases (see chap. x., p. 237): "The clinical features of chronic intussusception are often, and, indeed, usually, very ambiguous. No form of intestinal obstruction presents so many confusing elements in diagnosis; no form has led to more conspicuous errors in the right appreciation of the nature of the malady. Out of 55 cases collected by Rafinesque, many were never suspected to be examples of intussusception, and no less than 27 were the subjects of an absolutely wrong diagnosis." The same author finds but one case on record where the patient was relieved by fecal fistula, which in that one case emptied into the bladder. As there was no obstruction to the fecal movements in this case after the diarrhœa commenced, the stomach, as we should expect, was clean, normal, and empty, no fecal matter having been regurgitated or vomited. The symptoms while alive, and the subsequent discoveries after death, seem to suggest that the patient died of exhaustion.

124 West Ninety-fifth Street.

CASE OF REMOVAL OF A GLASS ROD, SIX AND ONE HALF INCHES IN LENGTH, FROM THE PERITONEAL CAVITY OF A WOMAN.[1]

By W. GILL WYLIE, M.D.,

New York.

Miss J——, aged twenty-five; family history is good. Previous history good, except for some trouble with kidneys in 1885. Menstruation always regular and painless up to October 18, 1891, and previous to that time had only a very slight leucorrhœa. Became pregnant after October 18, 1891, and on November 29th, during the morning, she introduced a glass rod, about six and a half inches long and about a third of an inch thick, having one smooth and one rough end, into the os uteri. She had considerable difficulty in doing this, but by sitting up and depressing the posterior wall of the vagina she could distinctly feel the cervix and the os uteri. After several efforts the smooth end was introduced, and finally it slipped in so far that, though she could feel the outer end, she could not grasp it. There was a little flow and some pain, but she walked around during the day as usual. That night she had a pain on the right side of the uterus when she lay down. The next day she went to work as usual, but had a slight flow in the afternoon. On lying down or sitting down the pain in the right side was increased, but it subsided while walking. On December 1, 1891, she had a physician examine her, but he said the uterus was movable and that there was no rod in her. She went about as usual, but the pain continued. On January 10, 1892, she miscarried, and, on account of hemorrhage following, she called a physician, who tamponed her that night, but removed it the next day. She remained in bed for a week, then went back to work. When she got up from the bed she noticed a lump on the right side, and when she pressed upon it she had a cutting pain in the left groin. She consulted me at my office on January 21st. She then had a very foul vaginal discharge. I sent her to my hospital, and had vaginal douches given till the odor was subdued. She was given ether on January 27th, and the uterus and its appendages were found somewhat fixed, and I thought I could feel the rod in the left iliac region. My assistants examined, but were uncertain; and when I examined again I did not feel the rod with certainty, and said that it had been displaced. On opening the abdomen the peritoneum was found congested, and there was much muddy serum, slightly tinged with blood, in the cavity. After breaking up the adhesions about the appendages the bleeding from the adhering left tube was so free and its lumen so obliterated that it was removed along with the left ovary. While feeling around on the left side, where I thought I had felt the rod, I found a thickening as if the rod had been embedded; following up this indication the rod was found in the left lumbar region. In looking for the point through which the rod had reached the abdominal cavity, I decided that it was just posterior to the junction of left tube with the fundus of the uterus. No scar could be found in the vagina. The patient took a douche of "sixty drops of carbolic acid to the quart of water" the night before she introduced the rod. She had some fever after entering my hospital before, but not after, laparotomy. She had intense pain when the bowels moved before the operation, but has no pain now, and is as well as usual.

[1] Read at the March meeting of the Northwestern Medical and Surgical Society of New York.

LEGISLATION ON MEDICAL AND HEALTH MATTERS IN THE VARIOUS STATES IN 1891.

By HENRY A. RILEY, A.B., LL.B.,

New York.

(Continued from p. 430.)

New Hampshire, New Jersey, New Mexico, New York, North Carolina, North Dakota and Ohio.—New Hampshire was one of the States establishing a State Board of Registration in Dentistry. This Board was to consist of three skilled dentists of good repute, residing and doing business in the State, and ten years' actual practice was required besides graduation from a reputable college.

It was provided that every person should register within six months who was in actual practice or had received a dental degree from a college or medical school, or who had a license from the New Hampshire Dental Society.

All other persons were required to be examined in reference to their knowledge and skill in dentistry and dental surgery. The certificates issued upon registration cost fifty cents, and the examination $5.

Any person falsely claiming a certificate, or pretending to be a graduate, or practising without a certificate, was committing a misdemeanor, and liable to a fine of from $50 to $100.

The law did not apply to any physician who is a graduate of the medical department of any incorporated college.

A law was passed forbidding the offering for sale of any adulterated drug or substance to be taken as medicine, or of any adulterated article of food or drink.

Drugs must be of the purity and quality prescribed by the United States Pharmacopœia, or they will be deemed adulterated.

Articles of food containing a less quantity of any valuable constituent than is contained in the genuine articles, or which have been colored or coated to conceal any damage, or which contain poisonous or decomposed substances, are deemed adulterated.

The State Board of Health is directed to make all necessary investigations, and vendors are directed to furnish samples sufficient for analysis on tender of their value.

If any one hinders the officers of the State Board of Health they become liable to a fine of $50 for the first offence, and $100 for the second. The State Analyst, before beginning his analysis, shall reserve and seal up a portion, and in case of prosecution this shall be delivered to the defendant or his attorney.

The name of the Hospital Association at Concord was changed to the Margaret Pillsbury General Hospital.

New Jersey.—In New Jersey an effort was made in counties not of the first class to provide in a private way for the insane poor.

It was directed that where there was in the county no hospital other than the hospital or sick ward of the county poor-houses, the Board of Chosen Freeholders might appropriate a sum not to exceed $2,500, "which shall be applied to the purpose of supporting and maintaining such patients as may be sent to any hospital or hospitals supported by private charity and located in such county, provided the sum so appropriated be used and applied for the benefit, comfort, and maintenance of such patients, inmates of such hospitals, as are residents of said county at the time of being sent to said hospital."

A law was passed abolishing the separate Boards of Managers in charge of the State Lunatic Asylum of Trenton and the State Asylum for the Insane at Morristown, and their control was vested in a single State Board of Managers, consisting of seven members. It was declared to be the "duty of the said Board of Managers to visit each county lunatic asylum in the State at least once in each year, and to inspect such institutions and their management, and to make in their annual report such recommendations as they shall deem necessary concerning such local institutions."

It was made unlawful for the manufacturers of chemicals to deposit any refuse on any vacant lot within one hundred feet of any human habitation under penalty of a fine of $25. If already deposited, and the offender refuses to remove it, he is liable to a fine of $10 per day.

When the milk inspector takes any milk for analysis, he shall divide it into two parts, seal each part in a suitable can, and tender the vendor one part.

The defendant could on the trial produce any competent evidence to show the per cent. of milk solids in the sample delivered to him.

The act to incorporate hospitals, etc., passed in 1877, was amended so as to provide "for the training, education, instruction, or preparation of persons, male or female, to act as nurses."

The charter of the Eclectic Medical and Surgical College of the State of New Jersey, at Jersey City, was repealed, as the institution was without standing or reputation.

New Mexico.—The legislation of New Mexico was meagre on all subjects, and contains little of interest to the profession. The Sanitary Board was given power to make and enforce regulations for the inspection of cattle intended for shipment or driven beyond the limits of the Territory. Railroads were forbidden to receive herds of cattle without certificates showing that brands and earmarks have been duly inspected.

A law was passed prohibiting burials within fifty yards of streams and running water, the former limit having been twenty-five yards.

An appropriation of $25,000 was made for the Territorial Insane Asylum at Las Vegas, to be applied to the erection of a suitable stone building.

New York.—In New York many measures were proposed and a considerable number became laws. One relating to the admission to practise is of considerable interest in view of the very recent but unsuccessful efforts to further amend it.

The 1890 law was changed so as not to apply to any student duly matriculated in any legally incorporated medical college of the State before June 5, 1890, if a certificate stating such matriculation, signed by the Secretary of the college, was filed with the Secretary of the Board of Regents of the University of the State of New York within three months after the passage of the law.

Section 834 of the Code of Civil Procedure provides that no physician or surgeon shall disclose any information acquired professionally, and a paragraph was added as follows: "But a physician or surgeon may, upon a trial or examination, disclose any information as to the mental or physical condition of a patient who is deceased, which he acquired in attending such patient professionally, except confidential communications, and such facts as would tend to disgrace the memory of the patient when the provisions of Section 834 have been expressly waived on such trial or examination by the personal representatives of the deceased patient; or if the validity of the last will and testament of such deceased patient is in question, by the executor or executors named in said will."

The law for the State Care of the Poor Insane, after serious opposition, was supplemented by an Appropriation Law, setting aside $454 850 for the purpose of providing accommodations at the various State Asylums for the Insane to be taken from the county poor-houses. The law directed 827 patients to be transferred as follows: 150 to the Utica State Asylum, 200 to the Hudson River Asylum, 200 to the Middleton State Homœopathic Asylum, 150 to the Buffalo State Hospital, and 125 to the Binghamton State Hospital.

The College of Physicians and Surgeons was authorized to convey all its property and assets to Columbia College, as that institution has made a satisfactory arrangement for the continuance of medical instruction.

The Legislature accepted the gift of the Medical Library of the Albany Medical College, and made it a part of the State Library.

An appropriation of $5,000 was made to provide for shelf-room and cataloguing.

A new charter was passed for the city of Buffalo, and new provisions made for the Board of Health. The Health Commissioner was to be a reputable and licensed physician of not less than thirty years of age, with an active experience as a practising physician of not less than five years.

The city was to be divided into eight health districts, with a physician in good standing in charge of each, and of the eight two were to be homœopathists.

Full and detailed directions were given for the collection and preservation of vital statistics, and rules laid down in regard to the prevention and suppression of epidemics, nuisances, etc.

A law passed in 1888 authorized the erection of a hospital in Brooklyn for the reception and treatment of persons suffering from contagious diseases, but it was found that the inhabitants of various localities selected for it were opposed to its erection, and the Legislature therefore passed a new law appointing three commissioners to consider the question of site and appraise the amount of damage any persons might suffer.

A law of considerable humane interest was that making it mandatory upon the Police Commissioners to appoint matrons at certain police stations, in whose charge should be placed all women prisoners, but under the direction of the officer in command.

There was a law passed in 1890 permitting the Commissioners to appoint matrons, but no action was taken under it and so a mandatory law was passed.

Two station-houses were selected at first, and now over a dozen have had matrons furnished. The law provides that arrangements shall be made to keep men and women prisoners entirely separate.

The project for establishing a botanical garden in New York City was carried through so far as legislative sanction was concerned, and the Park Commissioners were authorized to set aside two hundred and fifty acres in Bronx Park, when $250,000 had been raised by public subscription. When this sum or more had been provided the Board of Estimate and Apportionment was authorized to issue bonds for $500,000. A careless wording of one paragraph of the law seemed to permit the use of the interest and not the principal of the bonds, but it has been thought that a judicial construction of the whole law will permit the use of the main sum.

The objects of the law were stated to be: "The establishment and maintenance of a botanical garden, and museum and arboretum therein, for the collection and culture of plants, flowers, shrubs, and trees; the advancement of botanical science and knowledge, and the prose-

cution of original researches therein and in kindred subjects, for affording instruction in the same; for the prosecution and exhibition of ornamental and decorative horticulture and gardening, and for the entertainment, recreation, and instruction of the people." The scientific and educational part of the plan was placed in charge of the President of Columbia College, the Professors of Botany, Geology, and Chemistry in that institution, the President of the Torrey Botanical Club, the President of the Board of Education and their successors.

An effort has been made, but unsuccessfully, to change the *personnel* of the educational management.

The business and financial affairs of the corporation are placed under the control of a General Board of Managers, consisting of the persons above mentioned, the Mayor, the President of the Board of Commissioners of Public Parks, and not less than nine other persons to be elected by the incorporators.

The interest of the city of New York in the block between Forty-ninth and Fiftieth Streets, and Fourth and Lexington Avenues, was authorized to be released to the Woman's Hospital on the condition that the managers provide and maintain twenty-four free beds for poor persons residing in the city of New York.

Admission was to be obtained under ordinances passed by the Common Council.

The following appropriations were made for improvements, new buildings, etc., at various public institutions:

State Asylum for Criminal Insane at Matteawan	$76,461 33
St. Lawrence State Hospital	374,000 00
Middletown State Homœopathic Hospital	29,500 00
Willard State Hospital	37,700 00
State Custodial Asylum for Feeble-minded Women	16,000 00

North Carolina.—North Carolina enacted considerable legislation on medical matters, and among other things passed a law providing for anatomical material. The law says: "That for the purpose of aiding and promoting the study of anatomy in this State the Board of Directors of the Penitentiary are hereby directed to turn over to the State Medical School established at the University, or any other medical institution or college in this State, under such rules as they may prescribe, the dead bodies of all convicts except such as shall die of small-pox or scarlet fever, or any other contagious diseases, and which are unclaimed by relatives after due notice."

The law of 1889 relating to medical practice required practising physicians to register in the office of the clerk of the Superior Court by January 1, 1890. This period was extended in 1891 by amendment to January 1, 1892.

There were a number of amendments to the Pharmacy law. A person to be registered must now be a graduate of some College of Pharmacy, approved by the Board of Pharmacy, instead of the N. C. Pharmaceutical Association as formerly. The exception in regard to regular practising physicians was also stricken out, and they are now ineligible as registered pharmacists unless graduates of a College of Pharmacy. The mode of electing members of the State Board was also changed, and it was provided that the Pharmaceutical Association should annually elect one person who should be commissioned by the Governor.

The Legislature passed a comprehensive law regarding instruction as to the nature of alcoholic drinks and narcotics, with special reference to their effect upon the human system, and directed that this subject, in connection with the more general one of physiology and hygiene, should be taught like other branches in the public schools of the State.

It was directed that the text-books used in the lower grades should give at least one-quarter of the space to the nature and effect of alcoholic drinks, and that those for the higher grades should have at least twenty pages of instruction.

No certificates of qualification to teach in the public schools should hereafter be granted except after a satisfactory examination in the general subject of alcoholic stimulants.

Following out the general trend of the above law there was a large body of legislation directed toward the restriction of the liquor traffic. Probably not less than one hundred and fifty laws were passed forbidding the sale of spirituous liquors within certain distances of specified places which were usually school-houses or churches. These distances varied from one to five miles. A violation was termed a misdemeanor and punished by fine or imprisonment, or both. The Beulah German Reformed Church was distinguished by having a special law enacted in its favor to the effect that it was a misdemeanor for any one to exhibit himself drunk within two miles of the church when it was occupied for worship, or to use bad and indiscreet language while divine service was going on.

The penalty for the use of indiscreet language, not to mention the other offences, was a fine of not more than $50, or imprisonment not to exceed thirty days.

The name of the Western North Carolina Insane Asylum was changed to "The State Asylum," and arrangements made for admitting white inebriates under the same form of commitment as in the case of the insane, except that a specified time was to be inserted in the order.

This period was not to exceed twelve months, and could not be less than three months. If the Superintendent and Board of Directors think that treatment for a longer time than three months will be advantageous to the patient they can detain him for six months.

Only twelve inebriates are to be treated at one time.

There was a good bit of kindness and sentiment in one law passed by the Legislature, and that was the direction that the name "County Poor-house" should be abandoned and the institution styled "Home for the Aged and Infirm."

The sale or gift of cigarettes, or any substitute thereof, to a minor under the age of seventeen, was made a misdemeanor, and the offender is liable to fine and imprisonment.

North Carolina evidently believes in special legislation, for an act was passed allowing R. D. Jennings to register as a dentist within ninety days by complying with the law of 1887 and other laws.

Another act cast a protecting shield over Gaston County, by providing that if any physician should make any prescription for the purpose of aiding any person to purchase any intoxicating liquor contrary to the provisions of the law, he should be guilty of a misdemeanor and be fined at the discretion of the court.

The law of 1887 relative to the practice of dentistry contained a proviso that dentists who held a diploma from a chartered dental institute need not obtain a certificate from the State Board of Examiners. This proviso was stricken out by amendment in 1891.

North Dakota.—A considerable part of the legislation in this new State consisted in describing offences against the law and providing for their punishment. It was ordered that no horses, mules, cattle, etc., running at large could be branded between November 1st and May 1st, under a penalty of $100 fine and thirty days' imprisonment. The same punishment was made applicable to any person cutting off either or both ears close to the head of any horse, cow, calf, swine, etc.

It was declared to be a misdemeanor for any person to overload, overdrive, torture, deprive of food and water, expose unnecessarily to heat or cold, to leave unhitched or uncovered in cold weather or storm or in the night, any horse or similar animal.

It was also made a misdemeanor for anyone to keep dogs or birds for fighting, or to have a pit for this purpose.

A law was passed providing for a State Veterinarian and specifying his duties.

He was to investigate all contagious diseases among domestic animals, and to make visits of inspection to

localities where it was suspected that such diseases existed.

When animals were temporarily unloaded it was his duty to seize and inspect them unless the owner produced a certificate of health from the State Veterinarian or Examiner in another State. All animals coming into the State must be examined unless an affidavit is furnished that they had not been exposed to contagious diseases for ninety days.

He may order a quarantine, and if the case demands it shall report to the Governor, who shall issue such proclamation as is necessary. The salary of the State Veterinarian was placed at $2,000 and expenses.

Ohio.—An attempt was made to pass a Medical Practice law, but unsuccessfully, and there was little in the State of purely medical legislation. An act was passed, however, to permit physicians in the discharge of their professional duties to ride at their own risk on freight trains between stations where such trains stop, paying therefor the regular passenger fare.

The name of the Intermediate Penitentiary at Mansfield was changed to the State Reformatory, and detailed regulations were enacted for putting into operation the parole system.

All male criminals between sixteen and thirty, not previously sent to State Prison, and not guilty of murder in the first or second degrees, were to be sent to the Reformatory, and all sentences were to be general, without a limit, but the term was not to be considered as longer than the maximum now provided, or shorter than the minimum.

The Board of Managers were given power to establish rules by which prisoners might go on the parole in legal custody, and subject to rearrest for wrong-doing. If the Superintendent and Chaplain believe from the record and character of the prisoner that he will, if released, live and remain at liberty without violating the law, they are to report the case to the Board of Managers, who shall publish a notice that his case will be taken up for consideration, and any inquiry that the Managers may deem desirable may be made into his previous history.

If the decision is favorable the offender may be released, and a watch is to be kept over him so that he may be rearrested if necessary. If his conduct is satisfactory he may be recommended to the Governor for restoration to citizenship.

The whole system of discipline is to be reformatory, and carried out with the idea of restoring the criminal to an honest life.

All facts ascertainable regarding the previous life of each prisoner shall be entered in a book, and a memorandum made of his constitutional defects and tendencies, and suggestions in regard to the best probable system of treatment.

A uniform system of regulations shall be adopted, and some plan of marks or credits. The standing of each prisoner under this system shall be made known to him every month.

Appropriations were made for a new wing at the Cleveland Asylum for the Insane, costing $35,000, and for new buildings at the Dayton Asylum for the Insane, costing $30,000. The city of Cincinnati was also authorized to add one-tenth of a mill to the tax levy, for the purpose of improving and repairing the Cincinnati Hospital.

(To be continued.)

Leprosy in Spain.—Leprosy has been on the increase in different parts of Spain for some years past, and the extension of the disease has at last aroused the attention of the Government. On February 16th the Director-General of Beneficence and Sanitation sent a circular letter to all governors of provinces calling on them to take such steps as may seem necessary under the circumstances.

Clinical Department.

STRICTURE OF THE URETHRA IN THE FEMALE, AND REFLEX NEUROSIS FROM URETHRAL STRICTURE IN THE MALE.

By W. O. BRIDGES, M.D.,

OMAHA, NEB.,

PROFESSOR OF CLINICAL MEDICINE, OMAHA MEDICAL COLLEGE; PHYSICIAN TO ST. JOSEPH HOSPITAL.

In the MEDICAL RECORD of January 19th last, appeared an article from Dr. Fessenden N. Otis, on "Reflex Irritations and Neuroses from Stricture of the Urethra in the Female," and containing the histories of several cases which had, during several years of suffering, eluded the diagnostic skill of numerous physicians, finally to find relief at his hands after satisfactorily establishing a diagnosis of stricture. Professor Otis takes the ground that urethral stricture in the female is much more common than would be inferred from a reference to the books, and certainly, from the thirty cases which he states have come under his observation, and the statement by Emmet, third edition, page 257, "Stricture of the female urethra is rare in my experience, except as the result of violence, and it follows the use of nitric acid, other caustics," etc., his assumption must be correct.

The following case came under my observation several years ago, and, on referring to the literature of the subject at the time, I was impressed with the scantiness of the articles found, many of the works at my command containing not a single reference to it.

CASE I.—Mrs. G——, aged forty-five, German, married, the mother of several children, applied to me in the fall of 1886 for treatment. She had during the two previous years increasing frequency in urination, with tenesmus, which had latterly become so intense as to occasion great pain in the bladder, loins, and back. During the past four months she had noticed also increasing difficulty in voiding the urine, and required fifteen or twenty minutes of severe straining to complete the act. She had lost sleep on account of her suffering, and the demands of the bladder had become so constant as to interfere seriously with her household duties. She was nervous, irritable, sleepless, depressed, and had suffered so much that life was said to be no longer bearable. Her urine had been cloudy during the greater part of the time, and occasionally contained some blood. The flow was also said at times to be interrupted, particularly since she had experienced so severe straining as she had at the present time. A suspicion of chronic catarrh, with possibly stone in the bladder, prompted an examination, which revealed a lacerated perineum, an enlarged, somewhat prolapsed uterus, and cervical catarrh. The mucous membrane about the urethral orifice was congested, and the latter protruding and pouty. On making an attempt to enter the bladder for exploration, a No. 9 sound was arrested by an obstruction at about the middle of the urethral canal. A uterine sound met with the same fate, and finally a small pocket-case probe was passed into the bladder with some difficulty. A small sized bougie was then introduced, and a stricture located three-fourths of an inch from the meatus. Five per cent. solution of cocaine was injected into the urethra, and successive bougies passed until a No. 9 E. sound was admitted. Exploration revealed nothing abnormal about the interior of the bladder. The stricture was then dilated by sounds until a No. 15 E. was introduced, and the bladder emptied and irrigated with boracic acid in hot water. It was found to hold only two ounces with comfort to the patient, anything above this amount occasioning great distress and imperative desire to void the contents. The urine was found to be phosphatic, and contained shreds of mucus and pus in considerable quantity. On alternate days steel sounds were passed in increasing sizes to No. 21 E., which was used for several weeks longer. At each visit the bladder was thoroughly irrigated and its

capacity forcibly increased, until finally six ounces could be readily tolerated. From the first, improvement occurred, and became so marked in two months that she ceased treatment. During the following year I learned from time to time that she had no recurrence of bladder symptoms. Investigation revealed a previous gonorrhœa in the husband of this woman as a probable cause of the stricture.

In Dr. Otis's article attention is also called again to the remote reflex effects of urethral stricture, a subject upon which he has written vigorously, and to whose articles I am much indebted. The following case, recently experienced, presents a train of effects which are out of the ordinary reflex manifestations of stricture.

Case II. was referred to my clinic at the Omaha Medical College by Dr. Allison, in the latter part of December last, and presented the following history: James F——, aged thirty-four, Irish, unmarried, laborer, of nervous temperament; had never been ill until his present trouble began, four years before. In 1881 he contracted gonorrhœa, which lasted several months. In 1888 he began to experience tremors of the muscles of the forearms and hands, particularly noticeable when those members were extended. Very soon his legs became affected in the same way, and on attempting to walk he seemed to lose control over the moving leg, which rendered his gait unsteady. This condition increased to such a degree that his gait became constantly staggering, and he was soon obliged to give up active work. The annoyance intensified his nervousness and tremors, and his trouble was frequently attributed to an excess of alcoholic stimulants, by those with whom he came in contact. At the same time he noticed increasing difficulty in passing urine, the time required for the act becoming prolonged, and his power to forcibly eject the stream decreasing. There was also much diminution in the sexual desire, and erections were infrequent. He was much annoyed by very frequent seminal emissions, which had averaged two or three times weekly in the preceding four years. These were generally unattended by erections, and occurred during sleep. He had sought medical aid in various quarters, but had been led to believe that his case was incurable.

He was tall, thin, and exceedingly nervous. When attempting to speak, his words would come out in a jerky, irregular way, and on extending either arm or leg, violent tremors would occur. If such efforts were persisted in, the entire body became affected. On attempting to walk there was apparent loss of power over co-ordination, and he staggered along like a drunken man who had not yet lost all power over the muscles. He was unable to stand with the eyes closed and the feet in apposition, which symptom, with the co-ordinating defect, had strongly suggested the diagnosis of locomotor ataxia to the members of the college dispensary staff. The reflexes were much exaggerated, particularly of the patellar tendon. There was no anæsthesia, no history of numbness or prickling; there had been no eye symptoms; constipation had been and was quite distressing; there was no muscular atrophy or paralysis. His difficulty in urinating had continued to the present time. This combination of symptoms was not decisive of any organic spinal affection with which I was familiar, and the suggestion of reflex irritation occurred to me. On further questioning, he informed me that he had a long foreskin, which occasioned much annoyance from retained secretions. This was examined, and thought possible to account for the symptoms. Without home, friends or money, he was advised to enter the surgical ward of St. Joseph Hospital, where Dr. Neville performed circumcision before the college class. There was no improvement in his general condition or in the bladder. I then suggested that he be sounded for stricture, thinking possibly the bladder trouble might be the result of such, his history showing a previous gonorrhœa, although four years antedating his first symptoms. An examination revealed a contracted meatus, which was enlarged. Two strictures were then found in the pendulous urethra, which admitted no larger than a No. 13 French sound; these were divided with Otis's urethrotome. Sounds were then passed up to No. 20 E. Immediate improvement to his urinary difficulty ensued, and within a week he was decidedly less nervous; he had some control over the muscular tremor, and there was a marked change in his gait. In a month's time he could stand with his feet in apposition and the eyes closed, the body swaying a little only after a number of minutes. In two months he reported having been at work tending plasterers for two weeks, and was greatly improved. He could walk with steadiness, his muscular tremor had almost disappeared, the patellar tendon was only slightly exaggerated, there was return of virile power, and his nightly emissions had been much less frequent. The large-size sound was being introduced weekly, and he was taking a combination of iron, arsenic, and strychnine.

FORWARD DISLOCATION OF THE RADIUS AND ITS REDUCTION.

By THOMAS PARKER, M.D.,

EAST PORTLAND, ORE.

Miss D. P——, aged twenty, of Mount Tabor, Portland, called at my office and complained of having sustained an injury to her elbow on the previous day, in consequence of which she was unable to attend to her duties. A forward dislocation was diagnosed without difficulty. After several unsuccessful attempts at reduction, on the plan laid down in the text books, the patient was ordered home, but to return the following day, and in the meantime use hot fomentations to reduce the swelling.

Being then engaged with Professor Henry Coe in dissecting for his class, I hastened thither, and after considerable trouble produced a forward dislocation of the radius in the cadaver. In so doing my attention was attracted to a peculiar action of the radius on pronation and supination, the forearm having first been flexed; upon performing the latter it was interesting to see how the shallow, cup-like surface of the head of the radius screwed off the capitellum into the depression above the front part of the radial tuberosity, and how, upon pronation, it left its abnormal site, and gliding with a screw-like motion returned upon the capitellum. From the above experiment the following plan is easily deduced: For the easy reduction of a forward dislocation of the head of the radius, flex the forearm, then make firm pronation with one hand while the other follows the head of the radius into its normal site. This simple plan succeeded on my patient the following day at the first attempt.

The injury in this case was caused by powerful action of the biceps muscle, pulling the head of the bone out of its place, the forearm being strongly supinated, in the act of lifting a heavy weight from the ground.

Prizes of the Spanish Academy.—The Spanish Medico-Chirurgical Academy offers prizes of two hundred and fifty pesetas ($50), with the title of Corresponding Member of the Academy, for the best essays on the following subjects: 1. (Academy prize) Clinical Concept and Critical Discussion of the Modern Theories of Inflammation. 2. (Pedro Espina y Martinez prize) Critical Discussion of the Clinical Value of Changes of the *Timbre* of Physiological Murmurs and Rhythm in the early Diagnosis of Cardiac Disease. Essays, which may be written in Spanish, Portuguese, French, Italian, English, or German, must be sent before September 1, 1892, to the General Secretary, Señor Enrique Olivan y Sanz, Montera 22, Madrid.

Small-pox in Bombay.—There is a serious epidemic of small pox in Bombay. Twenty-three deaths from the disease are reported to have occurred in one week, and the malady continues to spread.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45 & 47 East Tenth Street.

New York, May 7, 1892.

REFORM IN ANATOMICAL NOMENCLATURE.

WE learn that Professor William Krause, of Göttingen, is going to Berlin to prosecute the task of securing a uniform anatomical nomenclature. He has undertaken this work at the instance of the Anatomical Society, and the expenses are to be borne by it and the Universities of Berlin, Vienna, and Leipsic. For many years this subject has been discussed, and reform advocated with conscientiousness and industry, by Professor Wilder, of Cornell University. If the distinguished professor's views had not been so radical and subversive he would have, doubtless, made a great success of his apostleship. As it is, he has been instrumental in securing a number of improvements in anatomical onymy.

The Association of American Anatomists has made two brief reports upon nomenclature, and has recommended the adoption of a few terms in nervous anatomy. Further reports are expected. The Association for the Advancement of Science has also appointed an International Committee on Biological Nomenclature, from which good results may be expected

The committee appointed by the German Anatomical Society in 1889, to superinte id the work, consisted of Kölliker, Oskar Hartwig, His, Kollmann, Merkel, Schwalbe, Toldt, Waldeyer, and Karl Bardeleben ; and their number was augmented in the following year by the election of Cunningham, of Dublin, Leboucq, of Ghent, and Romiti, of Pisa. France, England, and America are not represented. It is to be hoped that Professor Krause's work will not end in securing a Germanized uniformity, which will only add to the difficulties of learning anatomy on the part of students of other nationalities.

DIPHTHERIA DIGESTION.

THE investigations into the pathology of diphtheria are reaching a stage of completeness which is most satisfactory. The latest results have recently been presented by Dr. Sidney Martin, in the Gulstonian Lectures on the Chemical Pathology of Diphtheria. These lectures are not yet finished, but already Dr. Martin has apparently demonstrated facts of great and essential importance. Thus his experiments show that : 1. The bacillus diphtheriæ forms, from proteids, products of the same chemical nature as those found in the bodies of patients dead of diphtheria, viz., albumoses and an organic acid. 2. The albumoses formed by the bacillus in artificial cultivations have, in single and multiple doses, the same physiological action as those found in cases of diphtheria in man ; this action is the production of fever, of diarrhœa, and of loss of body weight, and of a progressive paralysis of the muscles dependent on a degeneration of the peripheral nerves. 3. The bacillus diphtheriæ is the primary infective agent. This organism liberates a ferment, the ferment is absorbed and digests the proteids of the body, producing the poisons which cause the diphtheritic symptoms. Diphtheria is essentially a form of digestion, then, and Dr. Martin presents the digestive table as follows :

Diphtheria Digestion.

Primary Infective Agent.	Secondary Infective Agent.	Digestive Products.	
Bacillus diphtheriæ	Diphtheria ferment (Roux and Yersin's poison) in membrane	Hetero-albumose Proto-albumose Deutero-albumose Organic acid	In membrane. In body.

The digestive process does not take place in the membrane on the throat ; nor, according to Dr. Martin, is the membrane the only source of the diphtheria products. Diphtheria digestion seems to take place to a considerable extent in the spleen.

THE HISTORY OF AN ABDOMINAL COMPRESS.

IF all laparotomists would write up the story of sponges, instruments, compresses, etc., left in the abdominal cavity, they would form a series of interesting, though perhaps somewhat tragic, tales.

A Paris surgeon performed abdominal section, in April, 1890, on a woman, aged forty-four, for a painful fibromyoma of the uterus. The uterus was removed with considerable difficulty, the pedicle fixed to the abdominal wound, the edges of which were then brought together. In order to protect the neighboring viscera during the operation, a certain number of sponges and gauze compresses—all carefully asepticized—were introduced into the abdominal cavity, each compress and sponge being held with a forceps. The same evening vomiting and pain came on, which lasted for six days, without any elevation of temperature. A month after the operation the woman was considered cured. In the month of August, however, pain, attributed to the presence of gall-stones, appeared in the right hypochondrium ; this disappeared in a few days. In September there was a renewal of the pains, which now involved the whole of the abdomen, and were accompanied by vomiting and tympanites, without fever. Palpation revealed the presence, in the region formerly occupied by the uterus, of a series of hard, movable nodules, resembling cancerous masses. A re-examination, under the microscope, of the tumor showed that it was a pure fibro-myoma. The patient remained in much the same condition for two months, when one day she passed per rectum a gauze compress enveloped in a hard fecal mass. All the unpleasant symptoms very soon subsided, and the woman has remained well since that event.

The Paris correspondent of *The Lancet*, who gives the above account, adds : That the occurrence of such a *con*

tretemps is not altogether unknown in the practice of the most careful surgeons is well attested. One operator now uses in abdominal sections fifteen compresses, hemmed in red, the enumeration of which is carefully made on the completion of the operation. A well-known surgeon once left a forci-pressure forceps in the abdominal cavity. The instrument remained in the cavity for eight months, and was then eliminated through an abscess which formed in the umbilical region. Another relates how he once left a sponge in the abdomen, the patient dying of peritonitis three days after the operation. He no longer employs sponges.

STOP SPITTING.

The modern gospel of prophylaxis teaches that phthisis can be abolished from the face of the earth if only people will stop spitting. Says Dr. T. M. Prudden :

"If the vile and increasing practice of well-nigh indiscriminate spitting goes on unchecked in nearly all assembling places and public conveyances ; if the misguided women who trail their skirts through the unspeakable and infectious filth of the street are to be admitted uncleansed into houses and churches and theatres ; if theatres and court-rooms and school-houses and cars are to remain the filthy lurking-places of contagia which their ill ventilation and their mostly ignorant and careless so-called cleaning necessarily entail ; if in sleeping-cars and hotel bedrooms the well are to follow consumptives in their occupancy without warning, or even the poor show of official disinfection ; if in ill-ventilated and ill-cared for dwellings the well must breathe again and again the dust-borne seeds of tuberculosis ; if no persistent warning is to be given to the ignorant of the dangers which lurk in uncleanliness—then our task will be most complex as well as difficult in limiting the contagiousness of tuberculosis."

Of course cleanliness and plenty of water are necessary ; but, after all, it is the expectoration which carries the germ and promotes the spread of disease. Spitting, it seems, is not only a vile, but an increasing, habit. This is an unfortunate social fact which reformers do not seem to have grasped, despite its noxiousness. Shall we not have to have a Society for the Prevention of Expectoration—except into sanitary spit-cups ? If one could stop the spitting habit, prevent the spread of consumption, and finally stamp it out, he would be greater than a tariff reformer.

A NEW HOSPITAL AND DISPENSARY.

There was opened last Sunday, in this city, an institution calling itself the Church Hospital and Dispensary. The special object of the organization is to centralize the dispensary work of the various Episcopal churches ; it aims also to pay especial attention to visiting patients at their homes.

There are, we are told, many cases where the removal of the patient from his home is, to say the least, unadvisable, either from the nature of his disease or because of the consequences to his family. To such cases this new institution intends to give special attention, and a corps of nurses and twelve visiting physicians will be provided to care for the patients in their homes.

In this way it is expected that much good will be accomplished, and a sisterhood, to be known as the Nursing Sisters, will be established, with the object of visiting and caring for patients in their own dwellings. It will probably be modelled after the similar sisterhoods connected with St. Bartholomew's and Guy's Hospitals in London.

Another special feature is a secretary, "who will devote his time entirely to investigating cases as they come in, and frauds and charlatans will receive little consideration."

Although the Church Hospital and Dispensary is an Episcopal organization, it will receive and treat patients of all creeds and classes.

Whether New York needs a new general hospital and another general dispensary is a matter of some doubt ; if it does, this new institution seems to be properly organized to supply the supposed want.

News of the Week.

Association of American Medical Colleges.—The third annual session of the Association of American Medical Colleges will convene at the building of the Detroit College of Medicine, at 3 P.M., Wednesday, June 8, 1892. Dr. N. S. Davis, President of the Association, will read a paper upon the following-named subject, to wit : "To what Extent should Clinical Instruction be Afforded the Student of Medicine in Regular Course ?" Another paper will be read by Professor V. C. Vaughn, of the University of Michigan, as follows : "To what Extent should Laboratory Instruction be Afforded the Student of Medicine in Regular Course ?" The discussion upon the papers will be opened by parties selected by the authors, and continued by the delegates *in extenso*. The indications point to a large attendance and a most interesting session, with the probability of representatives from a large majority of the colleges of the United States.

Was it Simply a Pleasure Trip ?—A subscriber from Havana, Cuba, writes : "Last week a party of thirty-eight physicians arrived from Florida. Did those gentlemen come simply on a pleasure trip, or did they have a scientific object ? If they were on a pleasure trip, the medical societies of Havana would have been glad to welcome them and show them every attention. If they had a scientific purpose, we regret their not applying to any of the medical and hygienic societies (Academy of Medicine, Society of Clinical Studies, Society of Hygiene) established in this city, which are the only ones able to give accurate information in regard to medicine or hygiene."

American Dermatological Association.—The American Dermatological Association, from Cushing's Island, Portland Harbor, will hold its next annual meeting at the Pequot House, New London, Conn., instead of Cushing's Island, as previously announced.

Dr. Ferdinand M. Pasco, of Red Creek, N. Y., died of acute peritonitis in that village on April 5, 1892. Dr. Pasco was fifty-two years of age, and had been actively engaged in the practice of medicine for nearly thirty years. He was graduated from the Medical Department

of the University of Vermont, in 1863, and immediately thereafter enlisted as a private in the One Hundred and Eleventh New York Volunteers, and was subsequently appointed Assistant Surgeon of the One Hundred and Twenty-sixth New York Volunteers, which position he held until the close of the war. He was widely known and highly respected, and he possessed to a remarkable degree those qualities of heart and mind which secured for him the well-deserved reputation of being a good and skilful physician.

Rapid Generation.—Dr. L. M. Sharp, of Minneapolis, Minn., writes: "On October 4, 1885, I attended a lady at the birth of her first child, and on July 19, 1886, I again attended her in her second confinement, just nine months and fifteen days between the birth of the children, both born at full time and well developed. She was a Scotch lady and had come to this city only a few weeks before her first child was born. Can any of the readers of the MEDICAL RECORD equal this?"—[We doubt if they can!—ED.]

The Congress of Criminal Anthropology will hold its meeting at Brussels in August and September of the present year. The careful and dispassionate study of criminals, from a purely scientific stand-point, is one of those distinguishing circumstances which mark off modern from mediæval and ancient times. A rough-and-ready promptitude was the chief characteristic of the behavior of all classes of persons toward known criminals, in almost all centuries and countries, before the dawn of modern science. But it is now recognized that the state and the public owe at least one duty, even to criminals, namely, that of taking the trouble to understand them.

A Successful Laparotomy in the Seventeenth Century.—The following note, in the "Diary of John Evelyn," would indicate that our professional brethren of two hundred and fifty years ago were not very far behind us in the matter of abdominal section for foreign bodies. It is dated Leyden, August 19, 1641, and reads: "Among a great variety of other things, I was shown the knife newly taken out of a drunken Dutchman's guts by an incision in his side, after it had slipped from his fingers into his stomach. The pictures of the chirurgeon and his patient, both living, were there."—*New York Medical Journal.*

Medical Advertising Pronounced Infamous or Disgraceful.—The whole question of advertising in connection with surgical and medical practice has been revived in England by the result of a long legal battle between a dentist named Partridge and the General Medical Council. It appears that in 1878 he was arraigned for advertising, and promised that he would not do so any more, agreeing to forfeit his diploma if he did. This promise, in its full sense, he did not keep, for in 1882, having become blind, he started a Ladies' Dental Association, which he advertised extensively over his own name. The Council took action against him in 1886, and decided to strike his name off the dentists' register. He went to law about it, and Mr. Justice A. L. Smith, who was confirmed by the Court of Appeals, granted him a mandamus to compel the Council to restore his name. Then he brought an action for malicious prosecution, and failed; and again, at the end of 1887, the Council struck his name off. Hence the present action, in which, first Mr. Justice Denman, and then the Court of Appeal—represented by the Master of the Rolls and Lords-Justices Lopes and Fry—have declared that the General Council is right. The Council is entitled, under the Dentists' Act, 1878, to erase the name of any person proved to "have been guilty of infamous or disgraceful conduct in a professional respect." This is the strong language which, according to the Council and the Court of Appeal, is applicable to Mr. Partridge, who has advertised. It is declared to be "infamous and disgraceful in a professional respect" for a dentist to announce himself in the newspapers. The decision has provoked much vigorous and unfavorable comment.

An Intestinal Tonsil.—Clado, in a monograph on the "Appendix Vermiformis," states that it functions as a gland, not an absorbing organ, and may be considered an intestinal tonsil.

Vivisection in Germany.—The Education Committee of the Prussian House of Representatives has lately had under consideration a petition from the "International and Hanoverian Association for the Suppression of the Scientific Torture of Animals," urging the absolute prohibition of vivisection. Both the House of Representatives and the Reichstag have already had the question before them, and the late Cultus-Minister, Dr. von Gossler, imposed certain restrictions on scientific investigators, in respect of experiments on animals, with the object of preventing any abuse. The majority of the Committee were of opinion that science could not dispense with vivisection, and that abuses had only been proved to have occurred in a few isolated instances. Such exceptional cases did not, however, in the opinion of the Committee, justify the total prohibition of vivisection. The House was therefore recommended to pass to the order of the day.

Venereal Disease in the Italian Army.—In 1888 Signor Crispi considered it advisable to abolish the enactments at that time in force for the regulation of prostitution. This step appears to have been quickly followed by a large increase in the prevalence of venereal disease both in the army and in the civil population, and the evil became sufficiently serious, in Signor Nicotera's opinion, to justify him in reversing the policy of his predecessor in this respect. By a decree dated October 25, 1891, the greater part of Signor Crispi's enactments, putting an end to the official registration of prostitutes, and to their compulsory examination and detention in hospital for treatment, etc., have been rescinded.

A Surgical Record.—The Museum of the Royal College of Surgeons will shortly be enriched with a singular, interesting, and extensive series of preparations, constituting what is, we imagine, a unique record in this department of surgery. Sir Henry Thompson completed last week his thousandth case of operation for removing calculus of the bladder and foreign bodies therefrom— 994 of the former and 6 of the latter. Every specimen has its history and the names of the persons, and usually the medical man interested in the case; the whole arranged in various tables, so as to give an exact statement in tabular form, grounded on the records taken in every case at the time in clinical books now in possession of their

author. The only comparable record is that of Civiale, but his collection was not classified or accompanied by clinical records or notes of the cases.

Management of Hospitals at North Brother Island.—At a recent meeting of the Board of Health, the following resolution was adopted: "*Resolved*, That upon due consideration of the testimony taken at an investigation in respect to the management of Dr. F. R. Percival, of the Riverside Hospital, at North Brother Island, in connection with typhus-fever cases, this Board concludes that the persons sick with typhus fever have been properly treated and cared for, and that no further action is necessary in the premises at present." Soon after the investigation referred to was commenced, Dr. Percival was removed from the charge of the typhus-fever cases and transferred to the charge of patients ill with other contagious diseases at North Brother Island, and he is still on duty in the latter position.

Cannibal Therapeutics.—Two Tartars in the neighborhood of Kazan have been sentenced to twelve years' penal servitude for the murder of a little girl six years of age. They had cut out her heart to give it to a sick person to eat, as a human heart had been prescribed by a mullah!

The Parrot Epidemic.—The Paris press has been publishing details of an alarming epidemic which broke out in three different centres in Paris. The disease was supposed to be a special form of epidemic pneumonia, and it was assumed to have been imported from Buenos Ayres through the medium of a cargo of parrots brought from that port by two Paris traders. Dr. Dujardin Beaumetz has now completed his investigation of the occurrence, and he exculpates the parrots, and states that we have had to deal with a pneumonic form of influenza. The only part taken by the parrots is probably the conveyance of the germs on their plumage. Several patients have succumbed to the disease, as also many of the parrots, but the surviving parrots are in a good condition.—*The Lancet.*

The Alleged Danger of Counter-irritation in Phthisis.—It is a not uncommon practice to put a blister or other counter-irritant over the apex of a tuberculous lung. According to Dr. Parrachia Anacleto, however (*The Lancet*), counter-irritation in localized tuberculosis is attended with great danger. Miliary tuberculosis spreads so rapidly from one organ to another, by way of the veins and lymphatics, that any irritation set up at the seat of the primary mischief cannot fail to increase the tendency of the disease to become general. Four cases which have recently come under his notice show this in a remarkable degree. Tuberculosis progresses slowly, but it allows of no violent remedies, and, he thinks, until some method of treatment more successful than either the injection of tuberculin, or cantharidate of potash, or the application of blisters has been discovered, the danger of causing general infection by their adoption will still remain.

Surgical Treatment of Gangrene of the Lungs.—A Paris surgeon, Dr. Périer, has reported (*The Lancet*) the case of a man, aged fifty-eight, whom he had treated surgically for gangrene of the lungs. The usual antiseptics given by the mouth had been all tried and found wanting, and the following operation was accordingly performed by M. Périer. An incision having been made in the second (left) interstitial space, the lung tissue, still covered by pleura, was seized with a pair of forceps. The pleura and the lung were then successively incised, about two centimetres of lung having to be traversed before the purulent cavity, which had a capacity of sixty cubic centimetres, was reached. The cavity was carefully disinfected, its parietes washed with camphorated naphthol, and finally its drainage guaranteed by two large tubes placed parallel in double-barrelled gun fashion. Cutaneous sutures were then inserted on each side of the tubes. The operation was performed on December 25, 1891, and union was complete on February 9, 1892, one drainage-tube having been removed on January 10th, and the other on January 14th. All cough, expectoration, and morbid physical signs having now disappeared, the patient, who is feeling quite well, may fairly be pronounced cured.

Statistics show that 47,000,000 of people die every year, and that to each and every one of these 47,000,000 must be allotted 2 × 6 feet of ground, making a total of nearly twenty-one square miles of the earth's surface that is each year taken up for burial purposes.

New Chairs and Professors at the Jefferson Medical College.—The Board of Trustees of the Jefferson Medical College, at their meeting, April 7, 1892, instituted a Chair of Clinical Gynecology, with a seat in the Faculty, and elected to the new chair Dr. E. E. Montgomery, who has been for a number of years Professor of Gynecology in the Medico-Chirurgical College. They also established the following clinical professorships, electing Dr. F. X. Dercum, Professor of Nervous Diseases; Dr. E. E. Graham, Professor of Children's Diseases; Dr. H. Augustus Wilson, Professor of Orthopedic Surgery; Dr. H. W. Stelwagon, Professor of Dermatology; and Dr. W. M. L. Coplin, Adjunct Professor of Hygiene.

A Layman's Mistake.—Dr. W. E. Forest writes: "In my article entitled 'A New Method of Artificial Respiration in Asphyxia of the New-born,' the word 'palpitation,' on page 398, should read palpation. A non-medical person undertook to correct the proof, and having never heard of palpation of the heart, felt sure that it must mean palpitation, and made the correction accordingly."

Virginia Medical Law.—The Supreme Court of Virginia has decided that the medical law of the State is unconstitutional. The case before them at which this decision was given was that of a largely advertised doctor from Boston, against whom complaint had been brought by the State Medical Board, alleging that he had no right to practise under the laws of the State.—*Boston Medical and Surgical Journal.*

Pan-American Medical Congress.—The following are the members of the Auxiliary Committee and Secretaries of Sections appointed from the West India Islands of different nationalities: *Danish West Indies.*—Member of International Auxiliary Committee, Dr. P. Mortensen, St. Thomas; Secretaries of Sections, Dr. Erichsen, St. Thomas; Dr. Kalmer, Santa Cruz. *Dutch West Indies.*—Member of Foreign Auxiliary Committee, Dr. J. J. Senior, Curaçao; Secretaries of Sections, Dr. C. Van Romondt, St. Martins; Dr. A. D. Jesurun, Curaçao.

French West Indies.—Member of Foreign Auxiliary Committee, Dr. Arnaud, Martinique. *St. Kitts and Nevis.*—Member of Foreign Auxiliary Committee, Dr. W. J. Branch, St. Kitts; Secretaries of Sections, Dr. A. P. Boon, St. Kitts; Dr. G. H. Mapleton, St. Kitts. *Leeward Islands.*—Member of Foreign Auxiliary Committee, Dr. A. G. McHattie; Secretaries of Sections, Dr. G. E. Pierez, Dr. A. E. Edwards, Antigua; Dr. P. Numa Rat, Domenica. *Barbadoes.*—Vice-President, Dr. Thomas Bowen; Member of Foreign Auxiliary Committee, Dr. Gaskin; Secretaries of Sections, Dr. C. E. Gooding, Dr. Cuthbert Bowen. *Trinidad.*—Vice-President, Surgeon-General S. L. Crane; Member of Foreign Executive Committee, Dr. J. A. DeWolf; Member of Foreign Auxiliary Committee, Dr. F. G. C. Damien; Secretaries of Sections, Dr. Beaven N. Rake, Dr. E. J. Read, Port-of-Spain; Dr. John Tulloch, Tobago. *Jamaica.*—Member of Foreign Auxiliary Committee, Dr. Da Costa.

Reviews and Notices of Books.

Essentials of Physics, Arranged in the Form of Questions and Answers, Prepared Especially for Students of Medicine. By Fred. J. Brockway, M.D., Assistant Demonstrator of Anatomy at the College of Physicians and Surgeons, New York. With 155 Illustrations. Pp. 330. Philadelphia: W. B. Saunders. 1892.

As a rule, text-books on physics are too large for the use of medical students. This work, though simply a compilation from various reliable sources, will consequently prove very useful. It contains all that one need know of the subject, is well written, and is copiously illustrated. The chapters on electricity and light are exceptionally good.

First Lines in Midwifery: A Guide to Attendance on Natural Labor, for Medical Students and Midwives. By G. Ernest Herman, M.B. (Lond.), F.R.C.P.; Obstetric Physician to the London Hospital and Lecturer on Midwifery; Physician to the General Lying-in Hospital, etc. Pp. 191. With 80 Illustrations. Philadelphia: Lea Brothers & Co.

The book is designed to give students and midwives such elementary knowledge as is needed for the safe management of natural labor. It succeeds admirably, and contains a large amount of practical information, much of which is original. Among the numerous illustrations are nearly a dozen excellent original ones.

Syphilis in Ancient and Prehistoric Times. By Dr. F. Buret, Paris, France. Translated from the French, with Notes, by A. H. Ohmann-Dumesnil, M.D., Professor of Dermatology and Syphilology in the St. Louis College of Physicians and Surgeons; Consulting Dermatologist to the St. Louis City Hospital; Physician for Cutaneous Diseases to the Alexian Brothers Hospital; Dermatologist to St. Margaret's Hospital, etc. Pp. 226. Philadelphia and London: The F. A. Davis Co.

After searching a couple of thousand volumes of books, in a half-dozen different languages, for facts about the history of syphilis, Dr. Buret presents the book in hand. It is a most interesting history of the subject, apparently disproving the generally accepted view that the disease had its origin in the famous epidemic of the fifteenth century. The book is not only exceedingly interesting, but it also has its practical side, and the practitioner will find much in it of value relating to the diagnosis and treatment of this too common disease.

A Treatise on the Ligation of the Great Arteries in Continuity, with Observations on the Nature, Progress, and Treatment of Aneurism. By Charles A. Ballance, M.B., M.S. Lond., F.R.C.S.; Assistant Surgeon to St. Thomas's Hospital, and Joint Lecturer on Practical Surgery in the Medical School; Surgeon to the National Hospital for the Paralyzed and Epileptic, Queen Square; Assistant Surgeon to the Hospital for Sick Children, Great Ormond Street; and Walter Edmunds, M.A., M.C. Cantab., F.R.C.S.; Resident Medical Officer St. Thomas's Home. Illustrated by 10 plates and 232 figures. Pp. 568. London and New York: Macmillan & Co. 1891.

The book in hand will become a classic. It is on a timely and important subject, and is the fruit of deep and thorough research. Many mooted questions are answered, and it makes a distinct advance in surgical knowledge. Some of the conclusions of the authors are as follows:

The rupture of the coats of an artery is by no means necessary for its occlusion, and the coats not being ruptured, hemorrhage is less apt to follow, although grave pathological changes may be in active progress.

The scar-tissue which occludes the artery is formed, not from the leucocytes of the blood, but from the plasma cells of the arterial wall. These cells do their work perfectly if the vessel be simply occluded.

With respect to the time taken in absorption of the various ligatures, chromic catgut holds the artery for a month or more, kangaroo tendon two months, and silk longer still. Reindeer tendon is about equal to chromic catgut, and peritoneal ligature to kangaroo tendon. Silkworm gut lasts longest of all, but the authors found it not easy to use. They were inclined to favor ox peritoneum, kangaroo tendon, or boiled floss silk.

In regard to antiseptics, they consider perchloride of mercury in solution the best for irrigation, while for dressing they favor Lister's cyanide of zinc and mercury gauze, wrung out in carbolic acid solution (1 to 40). Carbolic acid irrigation causes too free serous oozing, while sublimate dressings are apt to cause irritation of the skin.

With antiseptic precautions any vessel up to the size of the superficial femoral may be ligated by almost any method with success, but beyond that only the method of occlusion of the vessel without rupture of the coats is admissible. Suppuration is very apt to occur in the neighborhood of a great artery, and the consequent dangers are hemorrhage, aneurism, and gangrene. All three are more probable with the coats ruptured or injured than without.

In the matter of printing, the work is the perfection of art. The paper is excellent, the type large and clear, and the cuts and engravings remarkably fine.

A Practical Manual of Diseases of the Skin. By George H. Rohé, M.D., Professor of Materia Medica, Therapeutics, and Hygiene, and formerly Professor of Dermatology in the College of Physicians and Surgeons, Baltimore, etc. Assisted by J. Williams Lord, A.B., M.D., Lecturer on Dermatology and Bandaging in the College of Physicians and Surgeons; Assistant Physician to the Skin Department in the Dispensary of Johns Hopkins Hospital. Philadelphia and London: The The F. A. Davis Co. 1892.

This small volume is one (No. 13) of the "Physicians' and Students' Ready Reference Series." It is not intended for the dermatologist, but for the practical every-day work of those to whom this series is dedicated. Little attention has therefore been paid to the theoretical speculations upon pathology and etiology, as is stated in the author's preface. So far, however, as the requirements of the student are concerned, too little attention has also

been paid to those portions of these very necessary branches which are not any longer theoretical, and too much space has been taken up with treatment, which is very useful for the practising doctor, but not so valuable to him who is preparing himself for practice. Some formulæ are given in the text, and sixty-eight are placed together at the end of the book. While for the most part the therapeutical recommendations are very good and taken largely from personal experience, much that is recent and generally considered worthy of mention has been omitted. Treatment by electrolysis is made especially prominent, the author going so far as to recommend it as the method which will succeed best in removing the nodules of molluscum contagiosum "permanently, and without leaving a noticeable scar." These tumors are regarded as of sebaceous origin. One of the best features of the work is a chapter on the cutaneous manifestations of syphilis, to which eighty of the volume's three hundred pages are given up.

There is a good table of contents and index.

A Text book of Physiology. By M. Foster, M.A., M.D., LL.D., etc. Sixth edition. Revised. Part IV., comprising the remainder of Book III., the Senses and some Special Muscular Mechanisms; and Book IV., the Tissues and Mechanisms of Reproduction. Pp. 418. London: Macmillan & Co. 1891.

We recently reviewed Part IV. of the fifth edition of Professor Foster's work. The present volume is larger, and includes more. We have nothing further to add regarding the well known excellences of this text book; but we confess that the plan of publishing the work in various parts and books is confusing, and might lead to some annoyance. The student should remember to get the very latest, or sixth revised, edition.

Text-book of Comparative Anatomy. By Dr. Arnold Lang, with a Preface by Professor Ernst Haeckel Translated into English by Henry M. Bernard, M.A. Cantab. and Matilda Bernard. Part I., pp. 561. London and New York: Macmillan & Co. 1891.

There is much need of a thoroughly trustworthy and complete treatise on comparative anatomy. Gegenbauer's work has long been out of print, and no other work has appeared to supplement it or fill its place.

Professor Lang's reputation as an anatomist and teacher is sufficient guarantee of the value of his work, even if the success of the German edition had not evinced it. Dr. Bernard's translation is virtually a second edition of Lang's work. It covers the subject of protozoa, metazoa, platodes, vermes, and arthropoda. The book is copiously and carefully illustrated, many of the cuts being from sources not easily accessible to general students. The chapters are accompanied with a bibliography.

We await with interest the appearance of the remainder of the work, which, as dealing with comparative mammalian anatomy, will have more especial value to medical men. The translators have done their work with much pains, and have put the flowing phrases of the German writer into plain English.

A Dictionary of Treatment, or Therapeutic Index, including Medical and Surgical Therapeutics. By William Whitla, M.D, Professor of Materia Medica and Therapeutics in the Queen's College, Belfast, etc. Revised and adapted to the Pharmacopœia of the United States. Philadelphia: Lea Brothers & Co. 1892.

This is an excellent work. The author tells us that it grew out of his attempt to make a therapeutic index to his work on Materia Medica, but which he soon found assuming the proportions of a volume in itself. Each disease is taken up in alphabetical order, and its management, dietetic and hygienic as well as medicinal, clearly and intelligently discussed. Numerous formulæ are given as models and to exemplify the drug combinations, but adapted to the treatment of the disease in question; but the work is by no means a mere formulary. It is a scientific treatise on the means best suited to the cure of disease, and yet eminently practical. While the work is thoroughly original and no compilation, still the author does not insist upon his own views to the exclusion of others; but, after presenting his treatment, gives that favored by other authorities when it differs from his own. The book will be found very serviceable to the practitioner of medicine, whether young or old, serving to refresh his memory concerning old therapeutic methods, and to suggest to him not a few new ones.

Consumption: How to Prevent It, and How to Live with It. Its Nature, its Causes, its Prevention, and the Mode of Life, Climate, Exercise, Food, Clothing necessary for its Cure. By N. S. Davis, Jr., A.M., M.D., Professor of Principles and Practice of Medicine, Chicago Medical College; Physician to Mercy Hospital, etc. Pp. 143. Philadelphia and London: F. A. Davis. 1891.

Dr. Davis has prepared a book that is of great value to physicians, and also to consumptives themselves. It is simply the elaboration of rules and advice he had been accustomed to give to his patients, and is a complete handbook of the subject. He says he hopes much for the future of Koch's lymph and other curative drugs, but at present the best means of battling with the disease lie in the destruction of the sputum, a residence on dry soil in a properly selected climate, pure air, out-door work, exercise, avoidance of over-exertion, proper clothing, bathing, diet, etc. His chapters on climate, relating as they do almost exclusively to America, are of unusual excellence. The book is written in Dr. Davis's clear, concise style, and is so free from technicalities that it is a most excellent work to place in the hands of one's phthisical patients.

The New Cure of Consumption by its Own Virus. Illustrated by numerous Cases. By J. Compton Burnett, M.D. Second edition, revised and enlarged. Pp. 187. Philadelphia: Boericke & Tafel. 1892.

The book in hand is a homœopathic work. The author claims to have used the "tubercular virus" as a remedy in phthisis for the past five years, and claims the glory and fame now given Professor Koch. He obtains his remedy by trituration in spirit of a portion of tubercular lung, preferably taken adjacent to a cavity. This tincture is diluted according to homœopathic principles, and given by the mouth in almost infinitely small doses, at long intervals. Wonderful results are claimed, but the cases cited prove little. In not one of them is physical diagnosis spoken of, and in few of them is the diagnosis of phthisis at all evident.

Diagnostik und Therapie der Magenkrankheiten, nach dem heutigen Stande der Wissenschaft bearbeitet. Von Dr. I. Boas, Specialarzt für Magen- und Darmkrankheiten in Berlin. Leipzig: Thieme.

This is the second edition of the work which first appeared but one year ago. It is profusely illustrated, containing forty-eight woodcuts. Dr. Boas, whose reputation, both abroad and in this country, as a specialist, deserves especial credit for the enlargement and completion of this, one of the best, if not the best, book on diseases of the stomach. The book is divided into the Pathology, Diagnosis, and Therapeutics, and is as valuable to the specialist as to the every-day practitioner.

The chapters on the examination of the stomach contents, the tests for acid, the microscopical examination of different expressed stomach fluids, all deserve especial mention.

Balneo-therapeutics is also thoroughly discussed. The chapter on chemical tests for presence of acids and alkalies in the stomach, and also the importance of urinary

analysis, is thoroughly mastered. Another part, the special diagnosis and therapeutics of diseases of the stomach, will soon follow; and a third part, the treatment of intestinal disorders, will close the work of this author.

Medico Chirurgical Transactions. Published by the Royal Medical and Chirurgical Society of London. Volume the Seventy third. London: Longmans, Greene & Co. 1890.

This volume contains the "Transactions" for the year 1890. There are seventeen papers of the usual high order of merit, several of them finely illustrated with lithographic and process plates in addition to figures in the text.

Transactions of the American Surgical Association Volume the Ninth. Edited by J. Ewing Mears, M.D., Recorder of the Association. Philadelphia: William J. Dornan. 1891.

This volume contains the report of the meeting held in Washington in September, 1891, in connection with the Congress of American Physicians and Surgeons. The papers have already appeared in abstract in these columns in our full report of the Congress. The President of the Association for the current year is Dr. P S. Connor, of Cincinnati, and the Secretary, Dr. J. R. Weist, of Richmond, Ind.

Fourth Annual Meeting of the National Association of Railway Surgeons, held at Buffalo, N. Y., April 30, and May 1, 1891. Chicago: Published by the Railway Age and Northwestern Railroader.

This is the first publication in volume form of the proceedings of the Association. It contains, in addition to the papers prescribed at the fourth annual meeting, an historical sketch of the Association's list of members, and sixteen portraits of presidents, present and past, vice-presidents, and other officers.

Surgical Anatomy for Students. By A. Marmaduke Shield, M B. Cantab., F.R.C.S.; Senior Assistant Surgeon, Aural Surgeon, and Teacher of Operative Surgery, Charing Cross Hospital. New York: D. Appleton & Co. 1891.

This is a book that ought to be of great benefit to students in the medical school, and also to practitioners who have been so long away from the school that much of what they learned there has become dimmed and hazy. The author says in his preface that the book is intended for students to use with the living model; but that is no drawback, rather the contrary, for each one can serve as his own model; and if he then read a chapter of this book each night or morning, illustrating it on himself, he will soon find his anatomical knowledge much increased and his operative readiness and skill markedly improved.

Transactions of the American Association of Obstetricians and Gynecologists. Vol. IV. For the Year 1891. Philadelphia: William J. Dornan. 1892.

This volume, which contains the proceedings of the fourth annual meeting of the Association, held in this city in September last, is one that reflects credit on the Society. The papers are, many of them, of general surgical interest, and not of value solely to the obstetrical or gynecological specialist.

A Manual of Diseases of the Nervous System. By W. R. Gowers, M.D., F.R.C.P., F.R.S.; Consulting Physician to University College Hospital; Physician to the National Hospital for Paralyzed and Epileptic. Second edition, revised and enlarged. Vol. I, Diseases of the Nerves and Spinal Cord. Philadelphia: P. Blakiston, Son & Co. 1892.

The first American edition of this unexcelled authority on diseases of the nervous system was published only three years ago. It was then in one rather bulky volume, but is now in two, a change rendered necessary by the addition of much newer matter, and a decided improvement as far as the convenience of the reader is concerned. This first volume treats of the diseases of the spinal cord and of the nerves, the subject of general nervous affections and diseases of the brain being reserved for the second volume. The work has been thoroughly revised and largely rewritten, and is copiously illustrated with judiciously selected wood cuts, many of them original. Dr. Gowers's book is one of marked excellence and will long remain an authority. The second volume, it is announced, will appear shortly.

Traité pratique et philosophique du Pied-bot. Par E Duval, Lauréat de l'Académie des Sciences (Institut de France), Médecin en chef de l'Institut Hydrothérapique et Orthopédique de l'Arc de Triomphe, etc. Préface du Docteur Péan, Chirurgien de l'Hôpital Saint Louis. Paris: J. B. Baillière et Fils. 1891.

The name Duval is one that has long been associated with orthopedy in France, Dr. Vincent Duval being one of the pioneers in this branch of surgery, the one indeed who introduced tenotomy in France. His treatise on club-foot was long an authoritative work, and now that in the march of time its teachings have become antiquated, its author being dead, it has passed into the realm of classicism. The younger Duval very wisely made no attempt to revise this work and bring it up to the level of modern teaching, but has written a new treatise, and one that seems likely to occupy at the end of the century the position held by his father's work about the middle of this era. The subject of club-foot is very carefully and thoroughly discussed in all points relating to etiology, symptomatology, pathology, and especially treatment. There are upward of fifty wood-cuts of very moderate artistic merit in the book, but this is of small account when the other excellences of the work are taken into consideration.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Baltimore: Griffin, Curley & Co. 1891.

This volume contains the report of the proceedings of the semi-annual session held at Cambridge, Md., November, 1890, and of the ninety-third annual session held at Baltimore, April, 1891. At each of these meetings there were quite a number of papers read of considerable value and well worth being preserved in the form of the "Transactions."

Electrocution and the Healing Art.—*The Lancet*, commenting upon our remarks concerning the last execution by electricity in this State, says that "these are strong terms, but under the circumstances not one word too strong or too condemnatory. They surely will prevent any further medical participation in these unwholesome deeds. In this country, if medical art were degraded to such participation, the act would not only cause universal indignation against the offenders, but would force the profession at large to raise its powerful and humane voice in repudiation of any and every man in its ranks who dared to take a part in so grave an offence against the national conscience and professional honor."

A Bore-bell.—A Cincinnati physician has a secret office-bell, so says the *Annals of Hygiene*, which he calls a "bore-bell," and he says it is a great thing. When he is tackled by a bore, or when his lady visitors insist upon giving him the history of all their relatives and their ills, the doctor's foot suddenly touches a spring, which rings the "bore-bell," and in rushes a messenger with an important message or telegram. The visitors tedious tale is interrupted, and she or he leaves the office because the doctor is so busy you know. The same message or telegram can be used a great many times, and the doctor's callers never suspect anything.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 23, 1891.

H. P. Loomis M.D., Vice-President, in the Chair.

Carcinoma and Fibromata in the Same Uterus.—Dr. George C. Freeborn presented the above specimen. The uterus was removed by supra-pubic hysterectomy, by Dr. Clement Cleveland, at the New York Cancer Hospital, on June 15, 1891, the cervical portion being dissected away after the removal of the body of the uterus. The patient was a married woman, fifty years of age, who had no children, and who gave no history bearing on this condition, except that one year before there had been a severe uterine hemorrhage, and about this time she first noticed an enlargement of the abdomen. The mass weighed 2,200 grammes, the circumference at the base was 51 ctm., and its height 19 ctm. The organ was cut through transversely, and showed on examination a large cavity in the body of the uterus, surrounded by six myo-fibromata. The cavity contained only necrotic material, chiefly broken-down, smooth muscle-fibres. The other half of the specimen showed a large fibroid of the fundus of the uterus, and breaking through the capsule of the fibroid was a large fibromatous mass which protruded into the cavity. Microscopical examination showed that the whole length of the cervix was occupied by a medullary carcinoma which had invaded the whole mucous membrane of the lower third of the cavity of the uterus, and had encroached upon the muscular tissue so as to leave only a thin shell of this tissue externally.

Tuberculosis of the Lumbar Vertebræ.—Dr. R. H. Sayre presented the specimens, which consisted of three lumbar vertebræ removed from a child four years of age, who had died of general tuberculosis. When in the fresh state the specimens showed beautifully the early stage of bone tuberculosis, the second lumbar being chiefly involved At one point the process was just attacking the inter-vertebral cartilage. He also exhibited the left kidney, which was quite large, and its pelvis greatly dilated.

The child was first seen on September 2d, and it was stated that six weeks before this the first symptoms were developed, viz., pain in the head and along the spine, and inability to bend the spine. The family physician, suspecting disease of the spine, called an orthopedic surgeon in consultation, but as the latter considered the case one of malaria, treatment for this affection was begun. Not being benefited by this, the case was brought to Dr. Sayre, who diagnosticated tuberculosis of the spine, and possibly also of one hip. The child at this time was very anæmic, but presented no symptoms except those referable to the spine. There was no abdominal tumor to be felt, and nothing was discovered to account for the contraction of the right hip except the psoas contraction associated with vertebral inflammation. After about six weeks there was a sudden elevation of the temperature to 104° F., accompanied by photophobia, vomiting, and rigidity of the back of the neck, and at the same time an abdominal tumor was discovered a little to the left and above the umbilicus, which felt hard but resilient. The child was given bichloride of mercury for about two weeks. After about three days the meningeal symptoms disappeared. The tumor, however, steadily increased in size, and an examination under chloroform showed it to be freely movable. It was decided that the disease was too extensive to warrant an operation. Death occurred on December 12th. The autopsy showed an enormous mass of glands matting together the upper portion of the intestines, connecting them to the diaphragm and stomach. No small miliary tubercles were observed. There was slight jaundice shortly before death, and this was accounted for by a small band which was found pressing on the gall bladder. The liver and kidneys were enlarged. There was a large quantity of fluid in both pleural cavities, and one or two nodules were found in the apices of the lungs. Although the first symptoms were referable to the spine, this was found apparently much less involved than the other parts of the body. There had been no kyphosis, simply a lack of the normal hollowing in the lumbar region. Permission could not be obtained to examine the brain and spinal cord, and this was particularly unfortunate in view of the remarkable disappearance of the meningeal symptoms. When the specimen was shown before the Orthopedic Section of the Academy of Medicine, Dr. John Ridlon called attention to the prevailing belief that cases of meningitis which recover were not tubercular, and cited a case in his own practice which had been seen repeatedly by a number of eminent physicians, who agreed in the diagnosis of tubercular meningitis; and yet the boy had recovered, and was still alive.

Tricocephalus Dispar. — Dr. T. M. Prudden presented a specimen of the above. He was indebted to Dr. Brockway for the specimen, which he had removed from a subject in the dissecting-room, upon whom an autopsy had already been made. On this account, the existence of similar worms in the bowel could not be determined. Appearing through the skin on the mons veneris, was a reddish elevation, which was at first supposed to be a varicose vein, but which proved to be a filiform worm. Further examination showed it to be the tricocephalus dispar, one of the nematoid worms, in the same family as the trichinæ. It is the so-called "whip worm." Several worms were also found embedded in the muscles of one leg.

Dr. Prudden said that in his experience it was not at all common to meet with these worms, and it was exceedingly rare to find them outside of the alimentary canal. It was usually found with the head embedded in the cæcum. These worms are quite common in Europe; in Paris they are said to be found in about fifty per cent. of the cases examined. Although in this country the bowel is not always examined throughout its entire extent, it is customary to open the cæcum, and hence such worms could hardly be overlooked.

A number of the members stated that they had never met with this worm even in the bowel.

Perforating Ulcer of the Duodenum. — The above specimen was presented by Dr. A. T. Weston. The patient from whom the specimen had been removed was a truckman, fifty years of age, who three days before his admission to Bellevue Hospital had complained of abdominal pain; but this had not been severe enough to keep him from his work. On the day of his admission, the pain had suddenly become very severe. The upper part of the abdomen was retracted, the lower part distended. He died eighteen hours after admission. The autopsy showed a perforating ulcer of the duodenum, situated just beyond the pyloric valve. There was a slight exudation showing the beginning of a peritonitis. The abdominal cavity contained a large quantity of brownish fluid having the odor and appearance of stomach contents. The lungs exhibited the lesions of healed phthisis; the heart was normal; the kidneys were the seat of a chronic diffuse nephritis.

Dr. H. P. Loomis said that he had presented a similar specimen to the Society some time ago, and had taken occasion at that time to review the literature of the subject. He had found that these ulcers were usually situated three or four inches lower down than in the specimen just presented, and usually at the lesser curvature.

Yellow Fever and Revolutions.—If the belligerent statesmen of Brazil would inaugurate a campaign against the yellow fever, which has desolated a great part of their country, they might win the crown of triumphant statesmanship. It is not an unconquerable adversary. It has been driven from a good many places in the world through the enforcement of sanitary laws by courageous strategists.—*New York Sun*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, February 25, 1892.

ROBERT A. MURRAY, M.D., CHAIRMAN.

Floating Kidney and Diseases of the Generative Organs in the Female.—DR. J. SCHMITT read a paper with this title. He believed that one woman in ten who came to the gynecologist had more or less displacement of one kidney, usually the right. In examining for this condition the patient lay on her back, with the hips and knees well flexed; then, on pressing with one hand beneath the free border of the ribs, making counter-pressure with the other over the region of the kidney posteriorly, the patient taking a deep inspiration, the walls relaxed, the lower end of even the normally located kidney could usually be felt. During inspiration the kidney slipped downward, and if held during the height of inspiration could be prevented from slipping back during expiration. From simple loosening of the kidney to its lodgement in the pelvis all degrees of displacement occurred.

The author thought it was not necessary to distinguish between movable and floating kidney further than to say that floating kidney implied a high degree of movability. In advanced cases the organ lay in the iliac fossa or at the brim of the pelvis.

Two cases illustrating movable kidney were presented, one of the women having had one ovary removed for disease by a gynecologist, who, however, failed to discover the movable kidney. Patients with movable kidney felt best on rising in the morning, but after the trouble had lasted for some time rest in bed ceased to produce relief. Digestive disturbances were common, and there were likely to be manifold nervous disturbances, even unto mental derangement. But it was the author's intention to refer only to those symptoms which might exist in both movable kidney and certain diseases of the generative organs which had a similar etiology. In some persons no symptoms whatever resulted, in others there was a single disturbance, while in still others there might be the entire series of so-called hysterical symptoms. The same experience was had in sexual disorders. Certain genital diseases bore no direct relation to movable kidney, simply coexisting, while others showed a close relation. To the latter class belonged retroflexion and prolapsus of the uterus, cystocele, rectocele, and also chronic inflammations of the uterus and ovaries. To make this relation intelligible, it was necessary to take into consideration the etiology of movable kidney. The two factors on which the author laid most stress were, 1st, a change in the relation between intra-abdominal pressure and the elasticity of the abdominal walls, brought about by loss of flesh, tumors, etc.; and 2d, disappearance of fat about the kidney. Some authors had attributed greater importance to one of these causes, others to another. Several causes might act at the same time, the degree of influence produced by anyone varying according to the case. It was a clinical observation that women in whom the elasticity of the abdominal walls had been diminished by tumors or wasting diseases suffered comparatively frequently from movable kidney. It was equally true that this class of patients were also liable to be the ones to have uterine displacement or disease, cystocele, etc. The change in the circulation brought about by the causes already named still further aggravated the abnormal state of the kidney and generative organs. There was, then, nothing forced in the conclusion that movable kidney and chronic inflammation of the pelvic organs were largely due to the same cause. The influence of hydronephrosis and other special causes of displacement of the kidney were alluded to. They might also be a consequence.

With regard to treatment, it was obvious that he would be most successful who took both diseases into consideration, *i.e.*, movable kidney and whatever disease might exist in the generative organs. In the majority of cases the symptoms due to movable kidney could be relieved by a well-fitting elastic abdominal belt. The benefit was probably due to the support given the abdominal walls. The efficacy of springs and belts with a plate was questionable. Under heavy pressure the kidney was liable to slip down behind the belt. Still, a cushion might be attached to the belt with some advantage. Where other means failed, nephrorrhaphy might be resorted to; that is, fixation of the kidney by suture.

DR. GEORGE M. EDEBOHLS discussed the paper, and expressed the view that usually the chief cause of movable kidney was loss of fat about the kidney. He found movable kidney quite common—say in one out of twelve of all gynecological cases. It was an important factor in the causation of various disturbances in women. The pain was usually referred to the left, while the displacement was usually on the right side. Cardiac palpitation was apt to be marked. Floating kidney gave rise to fewer symptoms than simply movable kidney. In one of his patients whose perineum and lacerated cervix he sewed up and did Alexander's operation upon, the symptoms continued, then he performed nephrorrhaphy on the right kidney, with complete relief, but the symptoms returned when it was found the left kidney had also become movable. In performing nephrorrhaphy he slit the capsule proper and stripped it back half an inch on both sides, exposing the kidney structure the length of the organ, and secured firm adhesion by the extent of granulation surface following suturing of the capsule to the posterior wall.

DR. CURRIER wondered that, if movable kidney was so common, it had not been often discovered during the very numerous laparotomies performed in all parts of the world.

DR. AGRAMONTE thought percussion might be of some aid in diagnosis.

DR. SCHMITT said the pain was usually on the same side as the movable kidney.

Note on the Manual Rectification of Occipito-posterior Positions.—DR. EGBERT H. GRANDIN read the paper. He stated that he disclaimed dogmatism and aimed purely at suggesting recourse to a procedure which it was his conviction would alter the prognosis of, and lessen the dangers attendant upon, persistent oblique or sacro-rotated occipito-posterior positions. He freely granted that the large proportion of cases rotated anteriorly as soon as the occiput reached the pelvic floor, although even here it was at the expense of a tedious labor, and often also at the expense of the integrity of the pelvic floor. A minority of these cases did not engage, although the first stage had been somewhat prolonged and the uterus was becoming exhausted. Here the obstetrician should examine the pelvic brim with the entire hand, and finding the cause of lack of engagement to be—as he usually would—a posterior extended occiput, it seemed advisable, while the conditions were favorable, to rotate manually the fœtus anteriorly. This practice was certainly preferable to instrumentation in the pelvic cavity in the presence of uterine inertia (possibly), or fœtal exhaustion (possibly), or, worse still, a sacral position of the occiput. This argument was simply in line with the improving aim of obstetrics as an art—an aim which justified the deliberate election of each and every obstetric procedure at the most favorable time from the standpoint of both the woman and the fœtus. The clean, educated obstetric hand at the pelvic brim was a source of no danger to the woman, but rather one of positive safety, compared with the alternative to its use, this alternative being possible instrumentation after a tedious first stage of labor, in the presence of a protracted second stage, and with a fœtus held in the vice of a tetanized uterus. The procedure which he advocated was not radical, but simply preservative and conservative. In the instances in which the manœuvre failed, he thought the reason lay in the fact that the accoucheur rotated the head alone and not the entire fœtus.

Persistent Occipito-posterior Position Common.—Dr. Malcolm McLean referred to a recent article in a medical journal by which it appeared that the occipito-posterior position was not common. He believed this was an error, and likely to lead to oversight of a most common cause of accidents in labor. He was convinced that many cases of supposed disproportion between the size of the head and of the pelvic canal, resulting in injury, were really only cases of faulty position; that if the head had been rotated to the anterior position labor would have been normal and easy. An illustrative case was that of a woman who had gone through a number of confinements, all requiring embryotomy or craniotomy except one, in that instance a child being born without interference. This convinced him that the pelvis was large enough, and during his own sickness he instructed his assistant, who attended her in her last labor, to examine for the occipito-posterior position, rotate, and probably no difficulty would be experienced. It so proved.

Persistent Occipito-posterior Position Rare.— Dr. Marx said the article to which Dr. McLean had referred had been written by himself, and the opinion expressed that persistent occipito posterior position was rare was in accord with his own practice and that of a colleague who had seen many women in confinement.

Dr. A. H. Buckmaster had found that comparatively few doctors recognized the occipito-posterior position even when it existed, at least before the head had become engaged. In the majority of cases he had succeeded in maintaining the occiput anterior when rotated; sometimes it had returned. Results would be far better if manual correction were made.

Dr. J. C. Edgar approved of manual rectification, although he had had little occasion to practise it.

Dr. Jarman had seen three cases of occipito-posterior position with attempted rotation by hand, all with Dr. Coe. They had been unable to keep the head in the corrected position, and finally had resorted to podalic version.

Rotate the Child.—Dr. Ralph Waldo said that it was necessary not only to rotate the head, but also the body of the child, if one would not have recurrence of the faulty position.

Dr. Currier had been unable in one case to maintain the head with the occiput anterior after rotation, and had had to do version.

Dr. Brooks H. Wells agreed with Dr. Marx, that persistent occipito-posterior position in well-treated cases was rare. He had seen only four cases of occipito-posterior position, and in all had rotated successfully, either by hand early, or afterward by forceps.

The Chairman quite agreed with the author. He said it was evidently impossible to rotate the head with the hand after it had entered the pelvis, and as injurious consequences had often attended this position we should attempt to rectify manually before the head had become faultily engaged. Reference was not now made to cases which during the first stage gave no trouble, were not delayed; but to those which during this stage behaved unusually and called for examination. Then the head being found with the occiput posterior, it should be rotated. The introduction of the hand was necessary, and would enlighten one as to the relative size of the head and canal; necessity for any operation would enable one to do version, if necessary, or to rotate if that were sufficient. The position rarely persisted to the end, it was true, for the forceps usually converted it into the anterior at the outlet, but probably with a laceration.

Dr. Grandin said he had expected to hear more opposition to manual rectification. It had happened that he had seen a good many cases of occipito-posterior position. He thought it likely others had sometimes overlooked it. Nothing was more disagreeable than to be called to a case in which the head had become impacted in the pelvis with the occiput posterior. He impressed the necessity for rotating the body along with the head in manual rectification. As to high forceps, he would prefer podalic version.

SECTION ON SURGERY.

Stated Meeting, February 8, 1892.

Joseph D. Bryant, M D., Chairman.

Injuries of the Extremities.—Dr. Thomas H. Manley presented several patients in illustration of a paper which he read later. One was a man whose foot had been crushed and badly mangled in a street-car accident. The big toe had escaped much injury, and by using the skin and flesh on this to fill in the gap, he was able to avoid an amputation above the ankle, simply taking away the metatarsal bones and phalanges. The patient had a useful stump, although it was yet somewhat sensitive. The second case was one of foot crushed while getting off a train, only the little toe being spared. The remaining metatarsal bones and phalanges had to be removed. The man walked with scarcely a limp. The third patient presented was a carpenter, whose foot was crushed by a heavy timber. Consecutive amputation, instead of primary amputation, was resorted to, whereby all the tarsal bones were saved. One bone not being covered by skin, a secondary operation would have to be resorted to in this case. Still another like case was presented, and finally a boy, who had sustained a compound fracture of the radius in a dynamite explosion. He had been sent to Dr. Manley for amputation, but the hand and arm were saved by simply resecting the necrosed bone.

Ligamentous (Fibrous) New-Formation after Excision of the Elbow.—Dr. Charles A. Powers presented the specimen, which was obtained at autopsy from a young woman, who had died recently of pneumonia. She had had tubercular manifestations, and five years ago Dr. Wyeth had excised the knee for tubercular disease, obtaining a good result. Two years ago Dr. Powers excised the right elbow, taking away the humerus to above the condyles and a little of the radius. These parts were thoroughly disorganized, as were also the ligamentous structures. The patient regained good use of the joint, having considerable power in flexion, but weak extension. The specimen showed nicely the new ligamentous, or rather fibrous, structures.

Conical Stump Following Amputation in Children.—Dr. Powers also presented some specimens illustrating conical stump following amputation of the arm in children. The first was the conical stump amputated by Dr. Weir recently, in the case of a boy whose arm had previously been amputated for some injury. Dr. Furgeson had examined it, and stated that the sharp point of bone projecting through the skin had apparently come about by physiological elongation of the bone, producing pressure on the soft parts. This corresponded to the explanation given of these cases by Dr. Powers, in a paper once read before the Section. The other specimens illustrated the same condition. It taught us to make a long flap, and to inform the parents of the possibility of a conical stump forming later.

Dr. Powers also presented a melano-sarcoma removed from the lower jaw of a child.

Operation for a Case of Old Dislocation of the Inferior Maxilla.—Dr. R. H. M. Dawbarn presented a man who had been sent to him by Dr. Fitzgerald, of Bridgeport, for irreducible dislocation of the lower jaw of more than a week's duration. Some time before, the man had sustained a scratch by a nail, but became firmly impressed with the idea that he would suffer from lockjaw. After a time he was taken with tetanic spasms affecting a number of groups of muscles, but especially the depressors of the jaw. Antispasmodics had little effect, and the symptoms did not subside before the seventh day. Even during sleep the mouth remained open. The jaw did not return to its place, and an attempt was made to reduce

it, for now dislocation was suspected. Dr. Bacon and other distinguished men in the East failed, even with chloroform, and when the patient was brought to Dr. Dawbarn he did not repeat these attempts, but proceeded with an operation. This consisted in dividing the masseters just below the zygoma, pretty nearly their entire width, until the condyles were reached in their false position. Then efforts were made at reduction, which succeeded. Union took place by first intention. A short time before, a similar case was brought him, and he succeeded in making reduction after division of the masseter on one side only, but in the present instance his attempts failed until both masseters were cut. The only other case which he knew of had occurred under his partner, Dr. Brockway, while at Johns Hopkins Hospital. He had found no case recorded where dislocation of the jaw had been brought about by tetanus, but there were some where the cause had been convulsions or epilepsy.

After some discussion on these cases by Dr. Fitzgerald, the Chairman, and others, Dr. Manley read his paper:

Timely Consecutive Amputation or Resection in Serious Injuries of the Extremities.—Dr. Manley had stated elsewhere that primary amputation should not be resorted to in saving life unless all the important parts had been destroyed. When the parts were only extensively shattered without destruction of tissue, nothing was lost by waiting. Indeed, primary amputation was called for only in very exceptional cases. The principle of preservation should always be borne in mind. He had seen no ill-effect consequent on delay, whereas he had seen parts needlessly sacrificed by primary amputation. Besides the patients presented the fore part of the evening, he had had one case of bullet injury shattering the humerus, two of shattered tibia, and others, in which useful limbs were given by resorting to excision instead of amputation. Except where there was pus formation, he warned against the use of bichloride solution on bones, because of its irritating and injurious effects. He employed clear water. It was especially desirable when possible to avoid amputation to save important parts during the period of growth

Dr. Manley emphasized the need of saving the periosteum. Besides objecting to primary amputation, except in rare instances, he also impressed the importance of sparing all tissues possible, and particularly to avoid important articulations.

Dr. Dawbarn thought that Macewen had shown that while periosteum was important, yet the life of the bone might be saved without it. The introduction of decalcified bone where there was a gap was better than some other methods.

Dr. Reginald Sayre and Dr. Kammerer thought it was a well-established rule in surgery to save what one could, and Dr. Kammerer said he would apply the same rule in adults as in young subjects. As to primary amputation, if it could always be determined beforehand whether the parts were going to become gangrenous, the question would be made very simple. Secondary amputation, should it become necessary, might result in loss of life because of established sepsis, while primary amputation might have saved the patient As to an injurious influence of antiseptic solutions on the healthy tissues, he had not observed it.

Dr. Brockway said, with regard to saving all parts possible, that he had seen cases where too much had been saved, necessitating a secondary amputation because of the parts being in the way.

Dr. R. W. Townsend said that many patients came to the Hospital for the Ruptured and Crippled for whom instrument makers found it difficult and expensive to properly fit an apparatus, due to the fact that the surgeon had tried to save too much.

Dr. Arnold thought that where a man had to make his living, a greater risk to life might be taken in trying to save more of a limb.

The Chairman had always taught that as much should be saved as possible if it were useful. The surgeon should always aim to make a limb which would best serve the purposes of the patient. Like Dr. Dawbarn, who had just related an experience, he had seen cases in which the Mikulicz amputation had failed from a practical standpoint

Dr. Manley, in closing the discussion, said that Macewen's ideas regarding the periosteum were heretical, for he had told him (Dr. Manley) that he did not believe it possessed any power whatever in reproducing bone. The speaker had no confidence in the introduction of decalcified bone to fill gaps. Regarding age, he simply wished to state that the surgeon could accomplish more in the young than in advanced life.

Senn's Hydrogen Gas Test.—Dr. Dawbarn read a brief paper on this subject. He believed the profession generally in New York City did not approve of the gas test for perforation of the bowel, and, so far as he knew, it had not been practised on any living person in the city. Yet, since it had been resorted to in diagnosis elsewhere, he thought it worth while to narrate some experiments which he had practised on the cadaver. Having shot into the abdomen, he then pumped hydrogen into the rectum with the Davidson syringe, and held a torch over a tube penetrating the abdomen which would light the gas and give rise to a blue flame should any gas escape. All but two of twenty-two tests succeeded. In only three did the gas burn before there was marked distention, which showed that had the subjects been living the test would not have succeeded until the pressure had become so great as to interfere with respiration. In one of the cases of complete failure hard scybala occluded the opening. The other failure was due to the fact that the bowel had not been perforated. These and other experiments had led Dr. Dawbarn to the conclusion that when the abdomen had been penetrated above the umbilicus by a ball as small as 22-calibre it would be better not to operate, for some hours at least, but to give opium to prevent peristalsis and afterward salines; the reason being that in this locality the thickness of the bowel was likely to be such as to secure occlusion of the wound by swelling and plastic exudation. The patient was more likely to recover without exploratory operation than if the full length of the gut were searched for the opening, which might be necessary before it could be found. But if the bullet entered below the umbilicus, where the gut-walls were likely to be so thin as to preclude occlusion, however small the missile, one should always operate, and of course the use of the gas in this instance would also be uncalled for. Besides the danger of driving fæces into the peritoneal cavity, of causing undue pressure, of opening a wound which had been closed by swelling and exudate, there was a further objection to the use of the hydrogen gas, in that just the right mixture of it with oxygen might cause an explosion within the abdomen. This accident occurred in one of his experiments and was witnessed by several physicians. As usual, five minutes had been allowed to elapse after beginning the introduction of the gas into the rectum before the torch was applied to the tube leading into the abdomen, when an explosion occurred, evidently within the abdomen, the flame disappeared, and the distended walls fell back. The test was repeated, and twice more an explosion ensued. He did not doubt but what it would have proven fatal in the living subject. While objecting to any gas test, the author said he would prefer oxygen to hydrogen, since its use would be unattended by the danger just mentioned, and it had the advantage of being a cardiac stimulant and was rapidly absorbed by the blood.

Dr. Coley referred to Senn's paper on the subject, presented at the International Medical Congress, and to his own upon "Gunshot Wounds," printed in the *American Journal of the Medical Sciences*, and said he thought the objections to a gas test of any kind had been shown to be real.

Dr. Powers was glad to hear this vigorous protest against a measure which he believed had not been seriously considered in this city. As to the author's view that in wounds above the umbilicus it would be well to wait twelve or fourteen hours, he thought this was contrary to the teachings of most surgeons of New York, who advocated exploratory laparotomy in all cases.

Dr. Agramonte thought the same objection to the use of the hydrogen gas, including that of danger of an explosion, would also apply to oxygen, for the latter coming in contact with the hydrogen gas within the gut might likewise cause an explosion.

A Pioneer with the Gas Test.—The Chairman said that about two years before Senn came out with the hydrogen gas test he had made some experiments on the cadaver with atmospheric air. Two facts which he then encountered led him never to apply it on the living subject. They were, danger of driving liquid fæces out of the intestine into the abdominal cavity, and the overdistention of the gut, which would render its replacement very difficult after laparotomy.

Dr. Dawbarn thought Dr. Agramonte's objection to the use of oxygen gas, that it might also form an explosive mixture, was well founded, although the amount of hydrogen within the intestine was not likely to be sufficient to in any way magnify this danger. He was convinced that he stood not alone in the view that one should wait awhile before making exploratory puncture, if the ball were small and entered above the navel.

Permanent Preservation of the Records.—The Chairman made some suggestions with regard to the best way for permanently preserving the records of the Section, and the members were requested to submit to the Secretary a condensed report of cases and papers which they might present at the meetings.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BACTERIOLOGY OF VACCINE LYMPH—THE VALUE OF RAPID DILATATION OF THE UTERUS IN DIAGNOSIS AND TREATMENT—DEATH OF SIR WILLIAM BOWMAN, BART.—MR. LAWSON TAIT IN THE LAW COURTS—THE EDINBURGH UNIVERSITY SCANDAL.

London, April 2, 1892.

At a recent meeting of the Epidemiological Society, Dr. Monckton Copeman read a paper on "The Bacteriology of Vaccine Lymph," in which he gave an account of some recent researches which he had made. He remarked that some, reflecting on the failure of all attempts at the extra-corporeal cultivation of the virus, had suggested that it was not an organism but a chemical substance or euzyme. With a view of deciding this question he had repeated the experiments of Cohn and Burdon-Sanderson, from which they had concluded that the activity of the lymph resided in the solid particles rather than in the fluid portion. He did not consider his results conclusive, but he thought that the fact that the virus was reproduced in the living body through an indefinite series of transmissions was sufficient to prove that the active agent must be a living organism capable of self-multiplication. The immediate cause of the phenomena might be—and probably was, as in other diseases—a product of the microbes present in the lymph, but it could not be merely a chemical substance the quantity of which must be limited. In the hope of identifying the nature and action of the several bacteria he had undertaken a number of culture-experiments with calf-lymph. The inoculations were invariably followed by luxuriant growths—a feature common to all being that the parts of the growth most exposed to the air presented a marked coloration, more or less yellow or orange, especially in gelatines. Plate cultivations enabled him to identify: 1, Micrococcus pyogenes aureus; 2, M. cereus flavus, and 3, M. albus, or epidermis. He also thought he had obtained streptococcus pyogenes. Inoculations with pure cultures of these on human beings, calves, and rabbits only produced trifling inflammation, and nothing in the least degree resembling vaccination (one rabbit died from septicæmia after a free inoculation with a mixture of all four). Thinking that possibly the luxuriant growth of these might have destroyed the specific organism, he employed the method by which Kitasato had successfully eliminated foreign microbes and isolated the bacillus of tetanus, viz., subjecting the tubes to a temperature of 60° C. for various periods and making plate cultivations therefrom. His results were negative, and inoculations of calves with lymph from the tubes thus treated, and with fluid from the alkali albumin, were equally unsuccessful, showing that the specific microbes, if any, had also been killed. He had confirmed Dr. Husband's observations that the activity of vaccine lymph was not impaired by exposure to a temperature of 33° C.

A remarkable result was observed in the inoculation by Dr. Cory of a calf with lymph that had been subjected to a temperature of 48° C. No vesiculation followed, but the animal proved refractory to subsequent inoculations with fresh lymph of ascertained activity, showing that a degree of immunity had been conferred—possibly by the products of a microbe which had itself perished. Such a method would naturally preclude continuation by arm to arm vaccination, but it certainly seemed that lymph heated to 40° C. only, and thus freed from the organisms he had described, was considerably more energetic than fresh lymph, for the calf that, after inoculation with superheated lymph, had resisted the effects of fresh lymph of proved activity, yielded to a subsequent inoculation with the lymph thus "purified," exhibiting five well-developed vesicles. Dr. Copeman said he had found that the cloudiness that constantly appeared in stored lymph with impairment of its potency was due to an "aërobic" organism present in the lymph from the first, though in minute numbers. Careful exposure of the lymph to a regulated temperature checked or arrested the growth of this organism, and thereby enhanced the potency of the lymph, but always involved the risk of overdoing it and thus impairing its activity. The desired result could be attained by the simpler and safer process of dilution with a fifty per cent. solution of glycerine, even to the extent of twice or thrice its volume. Glycerine was known to act injuriously on many pathogenic organisms and had evidently the effect of inhibiting the growth of these "aërobes."

At the last meeting of the Medical Society Dr. Amand Routh read a paper on "Rapid Dilatation of the Uterus for Diagnosis and Treatment in cases of Uterine Hemorrhage," which was freely discussed. Dr. Routh urged that where there was profuse menorrhagia—and especially where metrorrhagia was also present—without obvious cause, the cavity of the uterus should be explored. Out of fifty-two cases, forty-two (eighty-one per cent.) were found to have a removable intra-uterine condition accounting for the hemorrhage. The best way of exploring the uterine cavity was to rapidly dilate the cervix with graduated bougies under anæsthesia. With rigid antisepsis there was practically no risk, and very rarely any subsequent pyrexia, unless malignant disease or salpingitis were present. Even where tubal disease was present or suspected, exploratory dilatation of the cervix for metrorrhagia of apparently intra-uterine origin was not necessarily contra-indicated, as salpingitis was often secondary to and aggravated by intra-uterine disease (antisepsis was here all-important). Where uterine fibroids were evidently present the immediate cause of hemorrhage might be a removable one, such as a co-existing polypus or a fungous endometritis, and therefore the uterine cavity should, when practicable, be explored before removal of the appendages or hysterectomy was entertained. In some cases dilatation alone sufficed to greatly relieve both the

hemorrhage and the pain. Dr. Routh also thought that if an exploratory dilatation were more often adopted prior to the employment of Apostoli's treatment, it would tend to a more exact knowledge of applicability of that mode of treatment and put its use on a more scientific basis.

Mr. Doran said the first thing to be satisfied of was the presence or absence of endometritis. The danger of this was its extension to the tubes and peritoneum, and the great advantage of dilatation and diagnosis was that many diseases to which women were liable could be thus nipped in the bud by suitable treatment. The difficulty with the uterus was that there was some of its membrane cast from it every month, but precisely how much no one knew; it was thus very difficult to say what was morbid and what was not.

Mr. Knowsley Thornton said he was sure of the value of antisepsis, but he did not see why antiseptics were all-important in pyo-salpinx cases, because in those it was impossible to protect the woman from sepsis. He quoted a case of fungous endometritis which had, for want of dilatation, been diagnosed as uterine carcinoma; hysterectomy had been proposed and would probably have been carried out but for an independent opinion which was obtained when the uterus was dilated and the condition diagnosed.

Dr. Hayes said he agreed with the author's general conclusions. He had only met with accident in rapid dilatation in one case and in this rupture of the uterus occurred and death ensued; the uterine tissue was found to be extensively degenerated, and he regretted not having used a sound beforehand, which might have revealed the condition

Dr. William Duncan thought rapid dilatation was preferable to gradual, and less risky—except in malignant disease of the fundus. He thought the uterus should be fixed with a vulsellum, as a case had been recorded in which the organ had been torn from its connections where dilators alone had been used. Operations for the removal of the appendages ought always to be preceded by preliminary dilatation. He related a case in which, having neglected to dilate the cervix, he removed the appendages for fibroid without stopping the bleeding; on subsequent dilatation he found a pedunculated fibroid as large as an orange, which he removed with the écraseur, with the result that the hemorrhage almost entirely stopped, though some intramural fibroids still remained.

Dr. John Williams did not think there was as much septic risk with tents as had been suggested. Rapid dilatation by bougies was better when pregnancy had recently occurred, but in women who had not been pregnant for a long time the risk was very great. It was not necessary to dilate a uterus for diagnosis so that a finger could be passed into it. Endometritis, for example, could be easily told by the way in which a sound passed gently over the surface of the mucous membrane produced hemorrhage.

Dr. Heywood Smith agreed that in many cases it was not necessary to go beyond a No. 18 in dilating. The operator himself should certainly hold the uterus, in order to estimate the resistance. He advocated the employment of Bell's dredge curette. Dr. Heywood Smith mentioned a case of pyo-salpinx, in which the whole tubeful of pus emptied itself into the uterus during the catamenial discharge; dilating and curetting might, perhaps, be of value in such cases.

Dr. Horrocks said there were cases in which dilatation of any kind was injudicious, and others—such as those in which the patient had not been pregnant for some time—in which it was better to use laminaria tents which had been soaking in absolute alcohol containing corrosive sublimate.

Dr. Champneys thought too much had been made of the idea that Hegar's method was the only antiseptic one. A laminaria tent could, with care, be made not only harmless, but the vehicle for the introduction of some antiseptic.

Dr. Lewers thought, rapid dilatation was not a method of universal applicability, but that it was of especial value where dilatation was required at no long time after a confinement, or miscarriage, or in cases of molar pregnancy. In cases apart from pregnancy, or in those who had never been pregnant, rapid dilatation often meant laceration, and for such cases dilatation by means of asepticized laminaria tents was preferable.

Dr. Amand Routh then replied and said he did not consider it safe to hurry too rapidly over the smaller sizes at the beginning of the process. Most cases could be diagnosed when the size of No. 15 Hegar was reached, and be only dilated further for operative purposes.

By the death of Sir William Bowman, the acknowledged head of British ophthalmology passes over to the majority. Sir William Bowman's professional career extended over more than half a century, and during the greater part of this period he was engaged in active work. His earlier research work was mainly histological, and especially in relation to the structure of muscle, of the kidney, and of the eye. "Bowman's sarcous elements," "Bowman's membrane," and "Bowman's capsule," are terms which survive as proofs of his original work in these regions. His later work was almost entirely devoted to ophthalmology, in which department he early attained a leading position. He took part in the evolution of modern ophthalmology, and his eminent services to the specialty were recognized by his unanimous election as first President of the Ophthalmological Society when the latter was formed in 1880.

Mr. Lawson Tait is very outspoken, and his candor has recently landed him in the law courts. Mr. Tait operated on a patient who had previously been subjected to electrical treatment. The operation proved fatal, and Mr. Tait thereupon wrote a letter imputing the result to damage to the tissues from sloughing caused by the electrical treatment. The doctor previously in charge of the case sued Mr. Tait for libel, but the matter was settled in court after some evidence had been given, by the withdrawal of all imputations on either side.

Professor Rutherford, of Edinburgh, has got into trouble with his assistant again, and the latter (Dr. Haycraft) is leaving—or rather, has been dismissed—as occurred with a preceding assistant. Professor Rutherford is obtaining an unenviable notoriety for his conduct, which promises to create quite an academic scandal.

PATHOLOGICAL LANGUAGE.

To the Editor of the Medical Record.

Sir: Although so much time has elapsed, allow me to add some facts and inferences, drawn from an experience of more than twenty-five years in the investigation and treatment of speech defects, to the article by Lillie E. Warren, M.D., in the Medical Record of February 21, 1891.

Several cases similar to those described by her have been under my care during the past few years. The most marked case perhaps was that of a boy nine years of age. Some of the vowel sounds were imperfect. He could not raise the back of the tongue to form hard *g* and *k*, or the tip to form the linguals, or draw back the tongue for the *s* and *z*, or bring together the underlip and upper teeth for *f* and *v*. Indeed every attempt at articulation was a failure. He had centred all his efforts to speak in the tongue, which in consequence had become much too large from over-exercise, and protruded beyond the lips. The result of ineffectual attempts in articulation was a peculiar language of his own, and in his way he talked incessantly and very rapidly; but while he understood all that was said by others, his own speech was wholly unintelligible except to his little sister, who understood him perfectly, and his mother to some extent. He was a very bright boy, learned rapidly, and as soon as he could talk well was much given to argument. He made us all aware of the faults of our language as we had never been before. When first acquiring a sound he was

inclined to use it constantly, as in hard *g* and *k*. Dog was *gog*, and take was *kake*, and so on. At first he alluded to himself in the third person, and omitted verbs and connectives. Most of his peculiarities are common to all that I have seen having this affection.

In some cases, not so extreme as this, where one articulation was substituted for another, the pupil would at first use both the acquired and the original sound; for instance, when "the" was called *me*, and "run" *lun*, at first it was *thme* and *rlun*. A boy staying with me now said *in* for is, and in learning called it *ins*, and it was only after much training that he was able to drop the *n*, so difficult it is to forget old habits. This same boy, sixteen years of age, was able to say but very few words, and the light on his face when he first said: "I do not know," and realized it was an answer to a question, was worth seeing. Most of these persons, though generally active, are in certain directions very helpless.

One could not dress himself without assistance, and would fall on the street if a very slight obstacle came in his way. The movements of another were like those of an old man, but as they learn to talk this strange helplessness disappears.

Among the vowels the long *i* is most likely to be deficient, and is usually sounded like *a* in arm. In some cases the final consonant is omitted. One girl talked like this: "Ah lē mah bā i ton" (I left my bag in town).

The conclusion in regard to the cause of this difficulty is that, as articulate sounds are not automatic, but must be learned by imitation, those born deaf or deficient in imitative power will not succeed in forming articulations except through special training.

The lisp, or the omission of the *r*, or the substitution of any one sound for another, are but slight symptoms of that which, exaggerated, causes the whole speech to become unintelligible, and which is stammering in the true sense of the term. Stuttering is muscular contraction at some point or points above the diaphragm, which hinders or stops the breath. Stammering and stuttering are often combined in the same individual.

A marked case was that of a boy, five years of age, who was under my care. He was unable to form some of the articulations, and it was very difficult for him to put any of them in the right place. *R* might be *w* or *l*, and long *i* was *ou*, as in out. One of his sentences was, "*Il i woup?*" (Is it ripe?) But his serious trouble was in the contraction of the throat muscles, which very frequently stopped the speech altogether. In a year's time the difficulties were all removed, but the conditions were so sharply defined in the beginning that it was fortunate his case was not neglected until they had become fixed. He was a remarkably bright boy, and at that early age so sensitive in regard to his speech as to be unwilling to speak to any stranger, though naturally inclined to be social.

The peculiar sensitiveness which attends most speech defects often becomes a mental disease, and is a serious complication. We may give as a general cause of stuttering that most persons speak with more or less unnecessary contraction at the points of articulation and in the throat muscles, acquired when learning to talk and by subsequent direct practice The corrective force of nature holds most persons inside the stuttering limit, but some temperaments are easily carried over, and then it is not easy to predict the end.

The children, both boys and girls, are taught to talk by women, most of whom speak with marked throat contraction, and in an abnormally high pitch of voice. Three boys stutter to one girl. May we not find the reason here? Many stutterers give evidence of chorea caused by the contraction. If the majority of persons talk under stuttering conditions, may not these conditions be at the bottom of a great deal of so called nervousness? I should like to know the views of others upon these points.

E. J. E. THORPE.

NEWTON CENTRE.

"THE COST OF A NAME."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of April 16th, under the heading of "The Cost of a Name," the editor of the MEDICAL RECORD was kind enough to quote an article of mine which was published in the *Therapeutic Gazette* for March. I write to state that I was unintentionally in error in regard to the relative price of diuretin (Knoll) and sodio-salicylate of theobromine. My error arose from the fact that the firm that sold me sodio-salicylate of theobromine charged me, through an error on their part, but thirty cents an ounce, when in reality they should have charged me a price identical with that charged for diuretin (Knoll) by McKesson & Robbins.

I understand that both products have been reduced very considerably in cost, and write this note to explain how the error occurred.

Very truly yours,
H. A. HARE, M.D.

PHILADELPHIA, PA.

ETHER AS A STIMULANT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your number for April 2d, I observe that in a paragraph headed "Ether as a Stimulant in the Temperance Hospital," you reproduce the substance of an "Annotation" in the *Lancet* quoting and commenting upon an anonymous letter in a London evening paper. Had the *Lancet* taken the precaution, before circulating a slanderous statement, to inquire into the truth of the charge advanced, it would have learned that at the meeting referred to, the allegation as to the use of ether instead of alcohol in this hospital had been conclusively rejected. The truth is, that very little ether, apart from its employment as an anæsthetic, is administered in this hospital was established to test, fully and carefully, the non-alcoholic treatment of disease, the medical staff are authorized to use alcohol when they regard it as necessary. Ether is employed as an anæsthetic, but otherwise is seldom administered, probably with less frequency than in other general hospitals.

The *Lancet* has inserted a correction of the mis-statement to which it gave such unfortunate currency, without making any inquiry upon the point.

I am, sincerely yours,
DAWSON BURNS, D.D.,
Hon. Sec. London Temperance Hospital.

AN EXPLANATION FOR SOME HIGH TEMPERATURES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A case is recorded in your last issue in which the temperature registered 116° F., and the mercury would have risen still higher had not the thermometer broken.

Other similar cases of extraordinary high temperature, exceeding by several degrees that of Dr. Alexander, are on record, attested by most careful and reliable persons.

It would seem quite impossible that any morbid process could cause so great a degree of bodily heat, or, in fact, that an individual could survive if subjected to it.

The most natural explanation of these cases is, that the observers have been deceived, or that their thermometers were unreliable. Yet they may be right.

It has occurred to me that the mercury may have been driven so high by mechanical pressure on the bulb of the thermometer.

In these cases, as far as I remember, the temperature has been taken in the axilla. It would not be a difficult matter for the patient, perhaps undesignedly, to compress the bulb with a good deal of force. If the glass were very thin and elastic, the mercury would be driven to the extreme end of the tube and the thermometer broken.

That an apparent rise in temperature will be so pro-

duced may be proved by pressing the thermometer bulb between the thumb and fingers, when the mercury will be seen to ascend several degrees.

WOOSTER BEACH, M.D.

NEW YORK.

New Instruments.

A SATISFACTORY TONGUE DEPRESSOR.

BY CHEVALIER Q. JACKSON, M.D.,

PITTSBURG, PA.

THE instrument to whose manipulation the hand has become habituated is the one that seems most perfect. If laid aside and another used for awhile, the first then seems awkward. Yet to depend on practice to gain skill with an instrument of defective construction is a mistake. The writer has more than once succeeded in getting a good view of the naso-pharynx in the rhinal mirror where others had failed—and he got it, not by superior skill, but by the use of a superior tongue depressor.

Nothing could be more awkward than many of the instruments sold under the name.

The requirements of a good tongue depressor are these: It should be simple, light, aseptic, comfortable for patient and operator. It should be of such construction that with it the tongue may be not only depressed, but drawn forward away from the posterior pharyngeal wall, thus to a great extent preventing retching. It ought to be narrow enough in the blade to go down between the two sides of the arch of the inferior maxilla without touching the alveolar process, and yet not so narrow as to slip sidewise when held by a patient with an obstreperous tongue, nor allow the lingual margins to curl up.

An ordinary spoon- or silver fork-handle, or a paper-knife answers some of these requirements; and for simple inspection of the fauces at the patient's house they have the advantage, especially in infectious cases, of avoiding the necessity of either troublesome cleansing or carrying home an infected instrument. But both a spoon and a paper-knife are out of the question in posterior rhinoscopy. Türck's depressor comes nearer than others to fulfilling all requirements, especially where the patient himself is called upon to hold it. But this is a clumsily constructed instrument. As ordinarily sold it is heavy; the blade is too wide to go down between the alveolar processes of the lower jaw without touching; the portion of the instrument coming out over the teeth is thick and too highly arched; the corrugations on the under surface of the blade collect infective material, and even with their aid the instrument will not draw the tongue as far forward as is desirable. The handle being made of horn or hard rubber, the instrument is soon damaged by immersion in boiling water. (This latter objection the Messrs. Tiemann tell me they overcome by "vulcanizing on" the hard rubber, insuring against separation of the handle.)

Of the other tongue spatulæ, those with hinges cannot be readily made either æsthetically or aseptically clean, and are not easily held by the patient. A hinge is no advantage anyway, for no practitioner who thinks anything of his patients, himself, or his family will carry about his person a tongue depressor—least of all one with a hinge wherein to collect infection. Instruments made entirely of hard rubber are distorted by immersion in boiling water, also by dry heat; and chemical sterilization is in any case unsatisfactory. In nose and throat work it is impossible to be thoroughly aseptic in our manipulations, but our instruments ought to be such that we are able to prevent the conveyance of infectious material from one patient to another. Twice the writer has examined at his office acute throat cases that proved to be incipient diphtheria. Had he not used a depressor the sterilization of which he could be certain he would have felt it his duty to destroy the instrument.

The general outline of this new instrument is seen in the cut. It is smoothly made of a single piece of steel, nickel plated; it is light, simple, and readily sterilized by immersion in boiling water. It has a sufficiently narrow blade, not roughened, but deeply concaved beneath, thus holding the moist tongue by atmospheric pressure that attaches it so tightly that the tongue may be drawn forward away from the posterior pharyngeal wall, thus to a great extent preventing retching. (In very sensitive fauces, slightly warming is a further preventive.) The portion of the instrument coming from the blade out over the teeth is thin and flat, and deviates to the right corner of the patient's mouth; thence it curves downward, forming a long handle well curved up into a hook below, to prevent the patient's hand slipping. After the operator has placed a depressor in position, the patient can depress his own tongue better than the operator can do it for him. For this way this new instrument is superior to all others (about twenty different patterns) tried by the writer. In position, it is easily held by the patient, and lies very flat and out of the operator's way, giving the maximum of available working space. For posterior rhinoscopy it is very satisfactory, as it draws the tongue forward, thus enlarging the oro-pharyngeal space. For this the patient is directed to push slightly forward on the handle.

The instrument is made in two sizes, the larger one for general use, the smaller for the small mouths of many women and most children. Those who do much nose and throat work will need both sizes. The smaller instrument the writer has found to be a constant necessity; but it will not do for large tongues. The average depressor to be had in the shops is worse than useless in children, on account of its wide blade.

The writer once had a patient with a roomy pharyngeal space draw downward on a Türck spatula in such a manner as to force the blade down back of the tongue, jamming the epiglottis tightly shut, threatening suffocation for a few moments. Such things are unpleasant, but they are impossible in the just-described depressor, which has the advantage of a shank going down behind the teeth, yet cannot get too far. In its low cost, cleanliness, simplicity and effectiveness it resembles the Sims vaginal speculum.

Negroes and Malaria.—It has been a tradition for centuries that the members of the black race were comparatively immune from malaria, but of late numerous practitioners in malarious regions within the tropics have adduced evidence against this theory. Dr. Jenkyns, of British Honduras, writes to the *British Medical Journal* of recent date that his experience of nine years in that colony has taught him that the negroes are very subject to intermittent fever, which is, however, very amenable to small doses of quinine, but that they also suffer occasionally from a bad type of remittent fever.

Compulsory Vaccination in Japan.—The local authorities in the prefecture of Tochiki-Ken have appropriated the sum of 4,996 yen to be used for prevention of small-pox, principally for public vaccination. The Governor has issued a proclamation ordering that all persons under forty years of age should be vaccinated, and that the vaccination should be repeated if it did not take the first time.

PRESENT PROBLEMS IN EVOLUTION AND HEREDITY.

THE CARTWRIGHT LECTURES FOR 1892.

(Continued from page 456.)

BY HENRY FAIRFIELD OSBORN, Sc.D.,

DA COSTA PROFESSOR OF BIOLOGY IN COLUMBIA COLLEGE, NEW YORK.

LECTURE III.—CONTINUED.

HEREDITY AND THE GERM-CELLS.

Conclusions.—Perhaps the most impressive result of our review of recent researches in evolution and heredity is the uniformity of life-processes throughout the whole scale of life from the infusoria to man. The most striking analogy is that seen in the laws of fertilization and conjugation, which are shown by Maupas's researches to have been established substantially in their present form at a very early period in the evolution of living organisms. Such uniformity furnishes a powerful argument for the advocates of the study of biology as an introduction to the applied science of medicine. Much that is now entirely omitted from medical education, because it is considered too remote, is in reality at the very roots of the science. To understand the disorders of life we should first thoroughly understand the essential phenomena of normal life. Of course we shall never see life as it really is, because there is always something beyond our highest magnifying powers; but we come nearest to this invisible form of energy when, with such investigators as Hertwig and Maupas, we strip the life-processes of all their accessories and view them in their simplest external form.

The problems of evolution are found to be inseparably connected with those of heredity. No theory is at all adequate which does not explain both classes of facts, and we have seen that the explanations offered by the two opposed schools—those who believe in the transmission of acquired characters and those who do not—are directly exclusive of each other. We should suspend judgment entirely rather than cease to gather from every quarter facts which bear upon the most important and central problem of the transmission of acquired characters. I have endeavored to point out the opportunities which medical practitioners enjoy of contributing evidence upon this mooted question. It must not be forgotten that while the inheritance of individual adaptation to environment is the simplest method of explaining race adaptation such as we observe in the evolution of man, we know absolutely nothing of how such inheritance can be effected through the germ-cells. We cannot at present construct even any form of working hypothesis for such a process. On the other hand, we have found how untenable is the alternative theory offered to us by Weismann, that it is solely natural selection or the survival of the fittest which

> ". . . shapes our ends,
> Rough-hew them as we will."

At the same time Weismann's conception of a continuity of germinal protoplasm, which we have found to consist in chromatin plus archoplasm, helps us over many of the phenomena of heredity, especially on the retrogressive side, and if it were not that we must also account for progressive and definite transformation in heredity, we might credit the distinguished Freiburg naturalist with having loosened the Gordian knot.

In summing up, the order of treatment followed in the lectures may be reversed, and we can begin with the germ-cells, and condense the more or less ascertained facts.

The Germ-cells.—1. The material substance of hereditary transmission is the highly coloring protoplasm, or chromatin, in the nucleus of the germ-cells, probably connected with a certain form of archoplasm, or dynamic protoplasm, outside of the nucleus.

2. Before conjugation and fertilization the hereditary substance of both the male and female cells is reduced to one-half that found in a typical cell. The substance is, however, first doubled and then quartered, the meaning of which process is not understood.

3. There is a difference of opinion as to whether the paternal and maternal hereditary substances, during fertilization, are fused or lie side by side; also as to how the substance is distributed through the tissues, whether *en masse* or by qualitative distribution.

Heredity.—4. No connection between the germ cells and body-cells is known, but the facts of heredity seem to render such a connection theoretically necessary. Several classes of facts connected with reproduction seem to support this theory.

5. The facts of heredity support the theory of a continuous and specific form of protoplasm as the basis of repetition of type.

Evolution.—6. The facts of evolution, both in present and past time, point to transformism by definite progression toward new types of structure in succeeding generations, opposing the retrogressive forces of heredity.

7. The theory (Natural Selection) of definite progression by the accumulation of fortuitous favorable variations is found not only theoretically improbable, but not to correspond with the observed laws of variation.

8. The laws of variation (anomalies) lend support to the theory of hereditary transmission of individual variations, but even this (Lamarckian) theory encounters many difficulties.

I think this is as fair a statement as can be made at the present time, and it rests upon a general survey of the whole field.

NOTE.—Bearing upon the experimental evidence for the hereditary transmission of mutilations, I have recently received, through Dr. Charles E. Lockwood, of New York, a letter,[1] in regard to some experiments upon mice, which were continued over more generations than those of Weismann, and with affirmative results:

"I selected a pair of white mice on account of their rapid breeding. I bred them in and in for ninety six generations, as they breed every thirty days, and when they are thirty days old they are able to reproduce themselves. I destroyed all sickly and defective ones by breeding only the fittest. I bred all disease out of them, and had a pure-blooded animal, larger and finer every way than the original pair. In breeding their tails off, I selected a pair and put them in a cage by themselves, and when they had young I took the young and clipped their tails off. When old enough to breed I selected a

[1] From A. J. S. Shiddell, Lexington, Ky.

pair from the young and bred them together, and when they had young I clipped their tails. I continued this breeding in and in, clipping each generation, and selecting a pair of the last young each time, in seven generations. Some of the young came without tails until I got a perfect breed of tailless mice. I then took one with a tail and one without a tail and bred them together, and by changing the sexes each time — a male without a tail, a female with a tail, and next a female without a tail, and a male with a tail—I was finally rewarded with all-tail mice."

There is such general scepticism now in regard to the inheritance of mutilations that it will be necessary to repeat these experiments in some well-known physiological laboratory. As told above, they seem to be perfectly trustworthy, but facts which go against a theory must be doubly attested.

A SUCCESSFUL CASE OF CÆSAREAN SECTION.

By T. GAILLARD THOMAS, M.D.,

EMERITUS PROFESSOR OF GYNECOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING SURGEON TO THE WOMAN'S HOSPITAL, NEW YORK.

ANTISEPTIC surgery in its long list of triumphs can point to none which is more illustrious than the "renaissance" of one of the oldest operations known to medicine, the Cæsarean section. Conceived and practised in the very earliest periods of the world's history, this procedure, eminently simple in all its details and offering itself as a precious resource where two lives are often at stake, has been, until very recently, deprived of most of its usefulness by the small percentage of success which has attended its performance. Thanks to the great discovery of the source of sepsis and of its preventive means, this "opprobrium chirurgiæ" has to-day assumed, and is destined forever to maintain, its place as one of the benign and most serviceable resources of our art. No physician who reads aright the signs of the times can for a moment doubt that the operation of the Cæsarean section will in the future yield almost as good results as those now yielded by laparotomy, performed for the removal of ovarian and uterine tumors; no progressive obstetrician will fail to recognize that it is about to relegate to the desuetude which it deserves that sad and disgusting procedure, craniotomy, with its revolting details, its terrible responsibilities, and its confession of the poverty of obstetric resource.

That the day will ever, or should ever, come when craniotomy will be eliminated from obstetric surgery I do not believe. It will always, and should always, have a place in the list of operations; but its place should be a small one; its claims as a resource should be to the last degree curtailed; its influence over the obstetric mind of the nineteenth century to the last degree minimized.

Resorted to, as it often is, as a screen for incompetency on the part of the obstetrician; practised, as it sometimes is, because its brutal simplicity puts it at the disposal of one unprepared to offer to his patient procedures requiring a higher order of education and skill, craniotomy is a crime, the commission of which will not be much longer condoned by the medical profession of our time. And yet, while expressing myself thus strongly on one side of the argument, I regard the man who declares that "under no circumstances would he perform the operation upon a living child" as one who acknowledges that he would culpably shrink from a duty which, in certain rare cases, is as plain as it is painful, and the neglect of which would, without doubt, place the responsibility of a woman's death at his door!

As I look back upon an experience of nearly forty years of obstetric practice, I recall none which has been so painful as that connected with decisions upon this point. Happy the man whose retrospect gives him no qualms of conscience, no painful memories in a field so pregnant with the possibilities of regret!

Certain it is that, with reference to this subject, the "old landmarks" have been materially altered. He who at the bedside to-day draws deductions from the old data; nay, even he whose practice is guided by the statistics of Cæsarean section accumulated just prior to the last decade, uninfluenced by the brilliant results obtained by Saenger and Fritsch, in Europe, and by Lusk, Kelly, and others in this country, is destined to a revelation, to an obstetrical awakening, which will make him aware of the fact that in this regard a new era has been established and placed upon a basis which promises to be an enduring one.

On January 24, 1892, Dr. J. J. Hull called upon me with the request that I would perform the operation of laparo elytrotomy for him upon a patient of his then in the Nursery and Child's Hospital in this city. I replied that, in view of the excellent results obtained in late years from the Cæsarean section, I looked upon laparo-elytrotomy as being no longer a warrantable procedure; that when I had advocated and practised it the statistics of Cæsarean section were so very bad that I felt justified in my support of it; but that now, in face of the excellent results which had attended the older procedure, I should give the preference to that operation, which I was very willing to undertake in this case.

Upon visiting the patient with Dr. Hull, I found her to be an English dwarf, twenty years of age, 4 feet 5 inches in height, who had lived in London, England, until three years ago, when she immigrated to this city. During her stay here she had supported herself by acting as a servant in a private family, and had enjoyed excellent health. This was her first pregnancy, and was an illegitimate one. By careful calculation she felt sure that it would reach its full term of nine months in a week from that time. She is a woman of good intelligence and a fair order of education, and we had every reason, not only from her statements, but from the physical signs of her pregnancy, the period of menstrual cessation, and the period of quickening, to put confidence in her deductions.

Photograph of mother and child, taken on the twenty-first day after Cæsarean section.

The following results of investigations and measurements of the pelvis, carefully made by different members of the visiting staff, alone, and in consultation, were recorded: *a*. Distance between antero-superior spines of ilia, 8⅝ inches; *b*, greatest divergence of iliac crests, 10½ inches; *c*, internal conjugate diameter of superior strait, 2⅝ inches; *d*, spinal column straight; *e*, extremities of long bones large.

These considerations: 1st, The apparently large size and vigorous state of the child; 2d, the fact that the full term of utero-gestation seemed to have been reached; and 3d, the narrowness of the conjugate diameter of the pelvic brim, led Dr. Hull and myself to believe that Cæsarean section would be a more appropriate procedure, in our patient's management, than an effort to deliver by the natural passages, with the great probability of having to

resort to craniotomy, with its certainty of death to the child, and its great dangers to the mother.

A consultation of the visiting staff of the hospital was called, and, eight votes being cast, it resulted in favor of the Cæsarean section. For the purpose of availing ourselves of the normal contractions of the uterus at full term, everything was prepared for the operation, and the house surgeon was directed to summon me and my colleagues as soon as labor fully set in. To our surprise, we waited just five weeks, the patient stoutly and positively declaring during this time, as she does at the present moment, that she was going to the end of the tenth month of gestation. Everything connected with the case leads me to feel quite sure that in this belief she is perfectly correct.

On the night of Sunday, February 28th, at ten o'clock, we were called to the hospital, and found the patient advancing into the first stage of labor. The os uteri was as large as a silver dollar, the cervical mucous plug had passed away, and uterine efforts were occurring every eight or ten minutes, and were strong and decided in character.

Before describing the operation, I will say that every antiseptic precaution known to science was adopted; not even the most insignificant was neglected. This will save me the trouble of again alluding to this matter.

The patient having been placed in the ordinary dorsal decubitus and anæsthetized with chloroform, I proceeded to operate in the presence of Professor W. T. Lusk, and Drs. J. J. Hull, Lambert, and Brattenall, and assisted by Drs. H. D. Nicoll, A. J. McCosh, Hayt, the house surgeon of the hospital, and Stewart Paton. The operation consisted of the following steps:

1. A long incision was made, extending from about two inches above the umbilicus downward nearly to the symphysis pubis, and passing through the peritoneum.

2. Three sutures of silk, twelve inches long, were then passed at the upper extremity of this incision, and left untied.

3. The uterus was then lifted out of the abdominal cavity, and, being carefully enveloped in a moist antiseptic towel, was given into the hands of my first assistant.

4. A large, flat sponge was then placed over the intestines at the upper extremity of the incision, and the abdominal walls were closed over it by tying the three silk sutures already mentioned as being left loose at this point.

5. A bit of elastic tubing was then passed around the cervix uteri, and a single knot made in it, but no constriction was practised.

6. A small sponge was then put in the lower angle of the wound, and the point of exit of the uterus from the abdomen was carefully and thoroughly protected against possible entrance of fluids by moist antiseptic towels and gauze.

7. The uterus was then opened, first by bistoury, and then the opening was enlarged by scissors.

8. The child's feet being then seized, it was removed; the cord was secured by clamps and severed, and the child, a large and vigorous boy, was given into the hands of Dr. Hayt.

9. The placenta, which was unusually large, was detached without effort, falling away like ripe fruit from a tree, and leaving less of a sign of its place of attachment to the uterus than any placenta that I have ever seen.

10. Slight hemorrhage occurring, Dr. McCosh tightened the cervical ligature and stopped it.

11. The uterus was cleansed with a sponge, and the cavity was dusted lightly with iodoform.

12. The uterine incision was then closed with deep sutures of silk, three to an inch, involving the uterine muscular tissue down to the mucosa, and with interven ing superficial sutures of the same material, one to every interspace.

13. The uterus was then returned to the abdomen; the sponges, already mentioned as left at the extremities of the wound, were removed; the peritoneal cavity sponged out; the omentum drawn down over the uterus; and fluid extract of ergot injected into the patient's thigh hypodermatically.

14. The abdominal wound was then closed exactly as after an ovariotomy operation, with silk-worm gut suture; the ordinary antiseptic dressing applied, and the patient put to bed, with directions that no food or drink be given, and that in case of severe pain the house surgeon should give morphia hypodermatically in moderate doses.

During the night Dr. Hayt found it necessary to use morphia three times on account of pain, but no other indication developed itself.

The after-history of the case was so uneventful that there is no reason for exhibiting a chart of it. Upon Dr. Hayt's examination of the child the following measurements were obtained:

SKULL.

Diameters.

	Inches.
Occipito-mental	5⅝
Occipito-frontal	5
Sub-occipito-bregmatic	3⅞
Bi-parietal	4
Bi-temporal	3⅝
Fronto-mental	3½

Circumferences.

Occipito-frontal	14½
Sub-occipito-bregmatic	13
Length of child	23
Across shoulders	5⅝
Across hips	6
Weight	10 pounds, 15 oz.

The operation of the Cæsarean section is one of signal simplicity and ease of performance. Were I asked upon what the future grand and glorious results of this operation are chiefly to depend, I should, with abiding confidence and implicit faith, reply, "Upon care;" *i.e.*, upon a conscientious and minute attention to details, more especially to those relating to antisepsis.

The operation which I here put on record prompts the following suggestions as to details:

1. I regard the lifting of the uterus out of the abdomen, and the partial closure of the abdominal walls before cutting into it, as a very important step, and one which conduces greatly to the prevention of the entrance of septic fluids into the peritoneal cavity. In no future case would I neglect it.

2. While undue haste should be avoided, rapidity of operation should be striven after. The demands even of a rapid operation upon the nervous system of the woman are necessarily great, and the tardy manipulations of an operator who wastes precious time in discussions, in asking opinions, and in illustrating views are greatly to be deprecated. The time is not propitious for a clinical lecture!

3. In lengthy operations I much prefer ether to chloroform; in this one, I prefer chloroform to ether, from the fact that vomiting subsequent to operation is a source of danger to the uterine sutures, and may force out fluids from the uterine cavity into the peritoneum, even if it do not disturb the sutures.

4. It is a matter of the first importance that the operation should be performed, not before nor after, but during the first stage of labor. Before full establishment of this, and after escape of the liquor amnii, the chances of success are greatly diminished.

Before closing this paper I venture upon a digression, which I feel sure that my readers will pardon. The woman who was the subject of this operation lay in the same room which was occupied by a patient of similar physical conformation, whom I delivered of a fine boy, fifteen years ago, by the operation of laparo-elytrotomy, and who left the hospital three weeks after the operation, carrying her lusty infant in her arms.

"The statistical results of laparo-elytrotomy," says Lusk, in his masterly work upon obstetrics, "are the saving of seven mothers in thirteen operations. But in no

one of the fatal cases were the conditions such as to render success a possibility." The operation failed to become a recognized and well-established surgical procedure, not on account of its own shortcomings, but because the modern improvements in the Cæsarean section have put that operation far above laparo-elytrotomy in ease, precision, and certainty of result.

In the name of simple justice it must be remembered that the recent grand results of the Cæsarean section have been obtained under the magical influence of "antisepsis;" while those of laparo-elytrotomy were obtained not only without that adjuvant circumstance, but at a time when the statistics of Cæsarean section were so very bad as to render it a rare procedure, and one limited in its scope to very desperate cases and the most forlorn circumstances.

Nevertheless, all things being considered, I close this article as I commenced it, with the frank admission that in view of the recent results obtained from the operation of the Cæsarean section, I should not feel warranted in performing laparo elytrotomy; which is tantamount to the confession that "it has been weighed in the balance, and (by comparison) found wanting."

A NEW ELECTRO-THERAPEUTIC ELECTRODE, WITH EXPERIMENTAL OBSERVATIONS.

By A. D. ROCKWELL, M.D.,

NEW YORK.

Sometime ago my attention was called to a new form of electrode, with a request that I test its action and give an opinion as to its value.

I have used it in perhaps a score of different cases in which pain, hyperæsthesia, and insomnia have been prom-

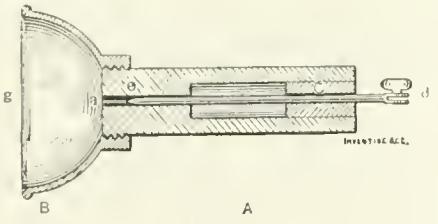

Fig. 1.

inent features; and, while I am not ready to pass final judgment upon it, yet the device seems to me to be meritorious, and to deserve a full description and further trial. That others, therefore, may be put in the way of testing this interesting contrivance, I ask place for it in the columns of the Record.

The object of this electrode is to combine special electro-therapeutic properties with an adjustable artificial resistance, the idea being to bring that portion of the body between the two electrodes under the influence exclusively of either the positive or negative pole of a voltaic battery. When two ordinary electrodes are applied to the surface of the body and a current of voltaic electricity made to pass from the positive to the negative pole through the intervening parts, the tissues immediately under and adjacent to the positive electrode are said to be under the polar influence of the positive pole, while those under and adjacent to the negative pole are said to be under the polar influence of the negative pole.

A point in the body approximately midway between the positive and negative poles is called the "neutral point," that is, a point where there is no change either in the acidity or in the alkalinity of the part, and where there is neither increased nor diminished irritability, neither catelectrotonos nor anelectrotonos.

In the drawings Fig. 1 is the electrode, while Fig. 2 represents the ordinary electrodes, and Fig. 3 this new electrode in use. Fig. 1 is a longitudinal section of this new electrode. It is a hollow handle composed of hard rubber. *B* is the body of the electrode (cup or funnel-shaped), also made of hard rubber; *g* is a porous cap, diaphragm, or partition for closing the larger opening of the funnel shaped electrode. *C* is a cylinder fitting the larger calibre *b* of the handle *A*; *d* is the conductor for connecting the electrode with the battery; *e* is the inner termination of this conductor, the end of which enters the small calibre *a* of the handle *A*. This conductor is preferably insulated except at the point, which is composed

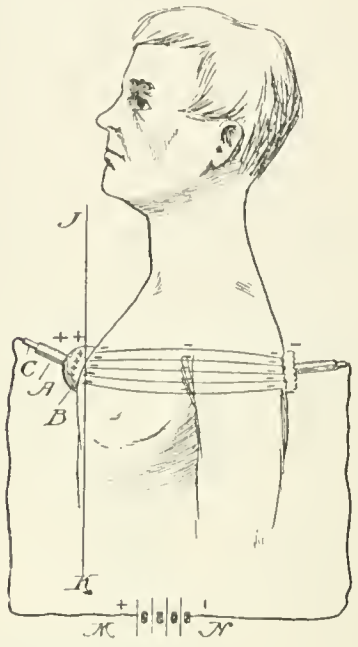

Fig. 2.

of some non-oxidizable material such as platinum or carbon. The conductor *d* is made to fit snugly the tube in the cylinder *C*, and, being adjustable, the point *e* can be adjusted to any position in the small tube *a*. By means of

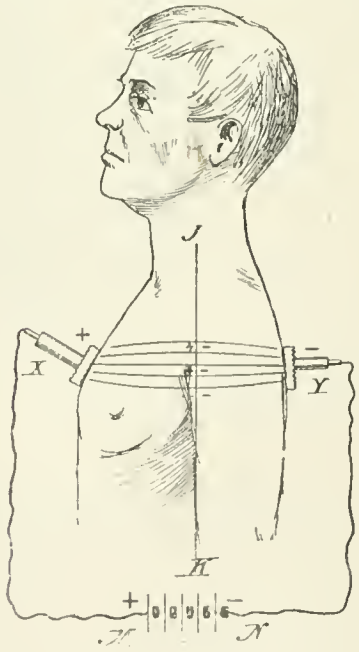

Fig. 3.

this facility of adjustment any desired resistance can be interposed in the circuit at pleasure. The funnel-shaped electrode is filled with some electrolytic fluid, as a very weak solution of bicarbonate of soda or potash or common salt. The conductor *d* may be secured in any desired position by means of the clamping screw.

Fig. 2 represents a portion of the body traversed by a voltaic current when the ordinary electrodes are used

X is the positive, *Y* the negative electrode. The vertical line *J K*, midway between these electrodes, indicates the neutral point. That part of the body between the positive pole and the neutral point is represented as being under the influence of the positive pole. This portion is said to be in a state of anelectrotonos or diminished irritability, and here are collected the electro-negative or acid-forming elements produced by the electrolytic action of the current. The part between the negative electrode and the neutral point is under the influence of the negative pole. and is said to be in a state of catelectrotonos or condition of increased irritability.

Fig. 3 illustrates what is supposed to occur when this new electrode is used in the application of electricity to the human body. The new electrode is represented as being connected with the positive pole of the battery, while an ordinary electrode is connected with the negative pole. The electrode may be filled with a weak solution of bicarbonate of soda, and the resistance is supposed to be equal to, or greater than, that of the body.

The neutral point *J K* is represented as having shifted from a central point in the body to the porous diaphragm of the electrode, and the whole of the body intervening is represented as being under the influence of the negative pole. In the use of this electrode it will be observed that the point of electrolytic action is supposed to be displaced outward from the part of the body immediately underneath the electrode, to the metal conductor in the electrode. The explanation of this is, that by using an electrolytic fluid not altogether dissimilar to that of the fluids of the body, and introducing into the circuit by means of said electrode an artificial resistance equal to, or greater than, that of the body, the polar influence of the voltaic current on the portion of the body adjacent is wholly eliminated, the neutral point is displaced outward, and the body may be said to be under the influence of the opposite pole of the battery.

As the depolarizing action of the liquid in this electrode is somewhat similar to that of the depolarizing liquid in certain fluid batteries, such as the Daniell. we might expect that the same laws would hold good in regard to the nature of the fluid used for obtaining the depolarizing effect in the two cases.

In the Daniell cell we have the diluted sulphuric acid in one compartment, separated from the copper sulphate solution in the other by the partition of porous earthenware. And as this arrangement is found practically to give the best results in preventing the accumulation of hydrogen gas, either at the surface of the copper plate, or at the porous partition (where bubbles of this gas may be observed to collect if a solution of another salt, such as the acetate of copper, be substituted for the sulphate), we may reasonably conclude that the electrolytic action within the cell is assisted by a certain similarity in chemical composition in the two liquids. In using this new electrode, the skin, and the porous diaphragm of this electrode represent the porous earthenware partition in the cell, while the fluids of the body and that within the electrode represent the two fluids used in the battery cell.

Reasoning from analogy, then, we might expect better results from the use in the electrode of a fluid similar in composition to the fluids of the body.

Now, it is probable, from the results of experiments in this direction, that the salts of the blood play the main part in the conduction of the current, the mineral acids, viz., sulphuric, hydrochloric, and phosphoric, being found underneath the skin at the positive pole, while alkaline compounds of sodium, potassium, etc., are found at the negative pole. Although the electrolytic action within the electrode can be obtained by the use of a simple solution of salt and water, as shown by testing the fluid within the electrode with litmus paper, it is possible that better results might be obtained by the use of a solution approaching more nearly the blood in chemical composition; and I am now using the following solution for charging the electrode:

℞. Sodium chloride..... gr. xxx.
Sodium bicarb..... gr. xx.
Sodium phosph..... gr. xv.
Sodium sulph..... gr. x.

To be dissolved in one pint of warm water.

Observation I.—Two ordinary sponge electrodes were applied to the body, with an electro-motive force sufficient to yield ten milliampères of current. In a few moments sharp, burning sensations were felt under both electrodes, but somewhat more severe at the negative than at the positive point of contact, while the redness excited was about the same under both electrodes. For the ordinary electrode connected with the negative pole I now substituted this new electrode, adjusted to a measure of resistance equal to, or a little greater than, that portion of the body to be traversed by the current, so that the neutral point might be supposed to be thrown outward into the electrode itself.

An increased electro-motive force sufficient still to yield a current of ten milliampères was now employed, with the result of exciting under the ordinary positive electrode a sensation of burning about equal in degree to that previously observed. Under the new electrode, however, connected with the negative pole the burning sensation excited, instead of being greater, was less than at the positive pole, as was also the redness occasioned.

Observation II.—A platinum needle connected with the positive pole was thrust into a piece of raw beef, and a small ordinary electrode connected with the negative pole was held in close proximity, and a current of 150 milliampères allowed to pass for five minutes. As is always the case, litmus paper showed an acid reaction at the positive pole and an alkaline reaction at the negative pole.

For the ordinary electrode at the negative pole the new electrode, charged with a weak solution of salt and water, was now substituted, and properly adjusted as to its resistance. An increased electro-motive force sufficient to produce the same amount of current strength as before was again allowed to operate for five minutes. The products of decomposition at the positive pole, when tested, revealed the same strong acid reaction as in the previous experiment, but at the negative pole, under the new electrode, the alkaline reaction was exceedingly faint. On the contrary, when we came to test the fluid inside of the electrode, where the neutral point was supposed to have been thrown, the alkaline reaction was distinct and positive.

Observation III.—It is well known that if a frog be decapitated the hind-legs will still retain their irritability to stimuli, and may be made to contract by an interrupted current from three or four cells. The hind-legs of a frog thus prepared were subjected to the influence of a weak galvanic current passed from the toes to the lumbar region of the spine. With the new electrode in use, connected with the negative pole, the muscles of the thigh exhibited diminished irritability and failed to respond to any ordinary strength of current. On the contrary, when the connection was made with the positive pole, the leg exhibited the phenomenon of catelectrotonos, and readily responded to a comparatively weak current.

It is a well established fact that in a circuit where metallic electrodes are used, electrolysis takes place exactly in the same way, as regards quality and quantity of the anions and cations, in whatever part of the circuit the electrolyte is introduced, and as the phenomena of anelectrotonos and catelectrotonos are usually described as resulting from the effects of the acids and alkalies, respectively, formed by the passage of the current, we naturally infer that the prepared electrode and the muscles of the frog's leg combine to form one homogeneous electrolyte in which the acids are deposited in the electrode and the alkalies in the muscles of the leg when the pre-

pared electrode is connected with the positive pole, as in the second experiment, or *vice versa*, as in the first experiment, when the electrode was connected with the negative pole.[1]

CÆSAREAN SECTION, REPEATED ON SAME WOMAN AFTER SIX YEARS, FOLLOWED BY RECOVERY, WITH A LIVING CHILD.

By A. H. F. BIGGAR, M.D.,

CLEVELAND, O.

(Reported by G. B. HAGGART, M.D.)

MRS. A. S——, a German, living at Salineville, O., aged thirty four; height, four feet, and weighing sixty-five pounds, had five impregnations; the three previous to the first Cæsarean section were terminated by craniotomy on account of the brimmed pelvis of the mother. The first section occurred December 16, 1886, resulting in

the delivery of a female child, by Sangers's method, the child weighing eight pounds.

In the present instance, at her home, seventy-five miles from Cleveland, labor pains began on Tuesday, February 16, 1892, at 3 P.M., and on the same night the waters came away. On Wednesday, at 3 A.M., she was put on a train for Cleveland—making the journey in a day car—the pains lasting until her arrival at 7 A.M. By mistake Dr. Biggar did not learn of her arrival on the morning train, and the consultation preceding operative measures occurred at 4.30 P.M. The medical class of the college were present, and the method was the same as the first, following the old line of incision.

The old operation had resulted in the adhesion of the entire uterine length to the abdominal wall. The length of time occupied was twenty-five minutes. The birth was "dry" in this case, on account of the early rupture of the waters, and the child weighed eight and one quarter pounds. In the first birth the fœtal heart-beat was 135, and the birth was wet, the position of the child in the uterine cavity, and the transparent waters surrounding making a most beautiful effect to the operator. When first operated upon, the father, who, like the mother, was of small stature, yet perfectly formed physically, objected to the removal of the ovaries. In the last one it was impossible to do so, on account of the most intimate adhesions of abdominal parietes to entire length of uterus.

Professor J. C. Sanders determined the fœtal heart-beat as 128—prognosing a boy. The case made a good recovery despite some bronchitic and erysipelatous symptoms, and returned home in the usual state of bodily vigor. The boy was christened—as a point of remembrance of the method by which rescued—Cæsar, and was a thrifty, well-nourished child.

The doctors present were: Drs. J. C. Sanders, H. Pomeroy, J. K. Sanders, Martha A. Canfield, G. W. Meredith, H. D. Bishop, G. B. Haggart, and Emily Barnes.

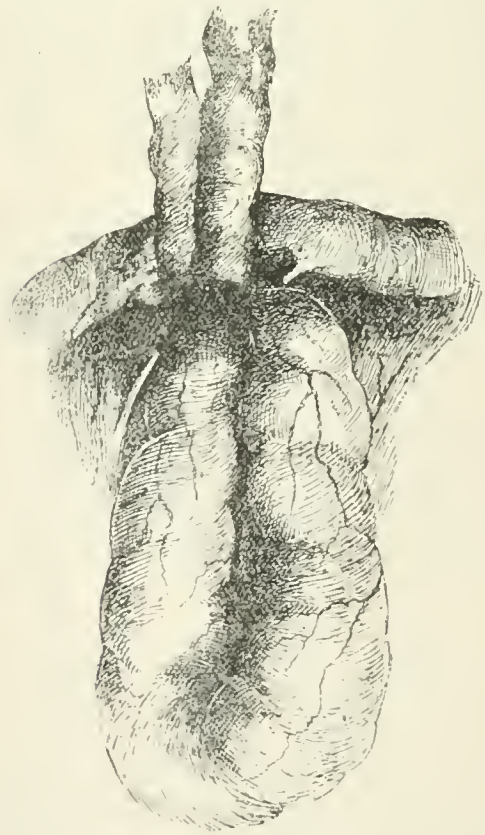
[1] This electrode was devised and is made by H. Bonis, 31 Stuyvesant Street, New York.

INTESTINAL OBSTRUCTION.[1]

By RICHARD DOUGLAS, M.D.,

PROFESSOR OF GYNECOLOGY MEDICAL DEPARTMENT VANDERBILT UNIVERSITY, NASHVILLE, TENN.

MISS SALLIE W——, of Gallatin, Tenn., is a frail, delicate blonde, about twenty two years of age. I submit the following brief history of her case for your consideration. Convalescent from an attack of influenza, on Wednesday, December 23d last, she was seized with severe pain in her abdomen, not localized at first, and relieved for the time being by the usual remedies; bowels responded



copiously to laxative. The following day, in the absence of her physician, Dr. Swaney, Dr. Woodson was called, who found her with intense abdominal pain, nausea and vomiting. The pain was most acute in right inguinal region, and seemed to radiate from that point over the entire ab-

[1] Read before the Tennessee State Medical Society, April 13, 1892.

domen. Pulse, 80; temperature, normal. Morphia was given freely. Symptoms unabated on Friday, when her physicians, Drs. Swaney and Woodson, in consultation, discovered a well defined swelling in the right inguinal region. McBurney's point of greatest tenderness was accurately located. There was some general tympany; persistent vomiting; pulse, 100; bowels had not moved since Wednesday, the first day of the attack. No effort, however, was made to move them, as the free response to the first purgation was deemed sufficient.

From the above rather familiar and other more minute facts, the diagnosis of appendicitis was made by the physicians in attendance. There being no improvement in her condition I was called, and reached her Sunday night at nine o'clock. Found her pulse 140, temperature, 99° F. Constant retching and vomiting. These were the symptoms indicating the extreme condition of the patient.

Examination showed the abdomen as symmetrically distended, the enlargement most prominent upon the right side; there was constant pain and extreme tenderness all over the abdomen.

Percussion outlined dulness over lower half of right lumbar, right inguinal, hypogastric, and into the inguinal region of left side. Remaining abdominal area highly resonant. These physical signs I could not quite reconcile with the diagnosis of appendicitis. I raised the question of intestinal obstruction, which it seems the free fecal evacuation after the onset of the symptoms eliminated. It also occurred to me the symptoms might be due to some acute complication in a hitherto undiscovered tumor. The evidence in this case did not sustain this view. Therefore, with no very definite opinion other than that there was some very active intra-abdominal trouble, which if not relieved would in a few hours terminate in the young woman's death, I determined in the face of her extreme condition to open the abdomen, search for, and if possible remove the cause.

Drs. Swaney and Woodson were positive that in the very early stage of the attack there was characteristic response to McBurney's sign. The tumor was most prominent and dulness most absolute in this locality, yet there were certain features in the case which did not accord with the diagnosis of appendicitis.

Owing to my inability to arrive at a more satisfactory conclusion, the operation was essentially exploratory in character.

Believing a lateral incision would lead more directly to the seat of trouble, I made a somewhat oblique incision in the right linea semilunaris. A pint or more of bloody serum escaped from the cavity, and a large coil of enormously distended intestine presented at the wound, greatly interfering with the intra-abdominal examination. On investigating the right inguinal region, and finding a free and floating appendix and flaccid, collapsed cæcum, the diagnosis was no longer doubtful. It was clear we had to deal with an obstruction in some portion of the small intestine. The field of operation was entirely occluded by enormous coils of intestines distended with fluid, rendering further manual examination practically impossible. Indeed this was not attempted, for it was observed that, owing to the extreme distension of the presenting coils, the serous coat had given away and there were two slight ruptures, about one-half inch in length and three inches apart, at right angles to the axis of the gut, involving only the peritoneal layer.

Determining at once to relieve the intestines of their contents, I drew the coil out of the wound as well as I could, packed about flat sponges for protection, and with scalpel I punctured the gut at the site of the partial rupture. At least two quarts of pea-soup-like fluid were ejected three feet or more from the patient—by the force of intra-abdominal pressure, of course, for all muscular power of the bowels was destroyed by the paralysis of over-distension. The intestines were now empty and flaccid. After closing the puncture and ruptnre with Lembert suture, further investigation was conducted without difficulty.

To facilitate examination and to protect from further injury by manipulation, the sutured coil of intestines was exventrated and enveloped in a warm napkin. Following by inspection the most congested coils of bowels, we soon came to the seat of obstruction, located high in the mesenteric attachment. The intestines were entwined and tangled in a most puzzling manner, forcibly reminding me of the knot in the fishing-line of my boyhood days. On careful scrutiny I discovered a round cord, about the size of a No. 6 catheter, attached to the mesentery, encircling and constricting the intestines, which were so matted by torsion and adhesive inflammation that it was impossible for me to trace the cord more than half an inch from the mesenteric origin. Satisfying myself it was a false ligament, I ligated close to the mesentery and divided. This, in a great measure, relieved the strangulation, enabling me to partially disengage the tangle. In doing so I discovered the distal end of the cord attached to the lateral aspect of the intestine. Ligating and severing this, I liberated the captured bowel, in all a loop of about three feet, deeply congested, with here and there deposits of plastic lymph, looking not unlike the membrane of diphtheria. At one spot on the line of constriction by the band, the wall of the intestine appeared almost gangrenous; so for safety it was folded in and the adjacent sound area stitched over it.

The cavity was now flooded with hot water, soft rubber drain introduced, and abdominal wound closed and dressed in the usual way. Almost immediately after putting the patient to bed she vomited quite a quantity of dark greenish fluid of distinct fecal odor. After this she appeared quite comfortable. Reaction was slow, yet the patient did moderately well until the fourth day; the wound was then examined, and found behaving badly, the edges were red and pouting, several stitches were removed, permitting a free discharge of sero-purulent matter; no doubt the abdominal wound was contaminated by intestinal contents at the time of operation. A mural abscess with some sloughing followed, protracting the recovery until the wound healed by granulation. The after-treatment was conducted entirely by Drs. Swaney and Woodson, to whose judicious care her ultimate satisfactory recovery was due.

It was with some pleasure and no little pride that I read the concluding lines of a letter in which one of those gentlemen, in speaking of the case, says, "In forty years I cannot recall a case which owes more to surgery."

An analytical study of the above recorded case will impress some important surgical facts upon the observer. The diagnosis, the pathology, and technique of operation may be reviewed.

Diagnosis.—The clinical history and early physical signs were pardonably misleading. The sudden onset, sharp abdominal pains localized in right inguinal region, free fecal evacuation after the advent of symptoms, quick pulse, and slight temperature; McBurney's point of extreme tenderness pronounced, and, finally, in confirmation of all, the development of a tumor in the cæcal region. The evidence thus presented would certainly warrant a verdict of appendicitis, yet in them we may see positive indications of intestinal obstruction.

Since pain was the most conspicuous symptom in the case, let us see if there is any positive diagnostic difference between the pain of appendicitis and of intestinal obstruction.

A sudden violent pain in the abdomen, most commonly in the right iliac fossa, is the "most constant first decided symptom of perforative inflammation of the appendix."—Osler.

Yet this positive symptom is generally preceded for hours, days, perhaps a week, by vague obscure pains—a sense of uneasiness. In other very occasional cases the patient is suddenly seized with severe pain in iliac region, with symptoms of collapse. The griping, colicky pains of

acute intestinal strangulation are always sudden in onset, never trivial, and are not heralded by prodrome. Patients may be "bent double with pain, and roll upon the floor," yet with all their agony, in which their constitution is profoundly impressed, they never pass *immediately* into that sudden and profound collapse which follows the violent pain of perforative appendicitis.

In acute intestinal obstruction the pain is referred to the "immediate vicinity of the umbilicus." In the majority of cases of appendicitis the pain is in the inguinal region, quite the exception for it to be referred to some remote part.

Tenderness.—This is an early, constant symptom of appendicitis in all stages or forms. It may be merely the local increased sensitiveness of the mild catarrhal form, or it may have the general tenderness of peritonitis consequent upon perforation. In acute intestinal obstruction tenderness is not an early symptom. Treves says it may never appear; usually, however, it develops with onset of local or general peritonitis. When limited it is usually over the seat of obstruction. McBurney's point of localized tenderness on deep pressure is held to be almost pathognomonic of appendicitis.

Upon the authority of Drs. Woodson and Swaney, the above detailed case in intestinal obstruction responded most beautifully to the McBurney test. We cannot expect to find the appendix in the same position; this fact, says Hoffman, "forever blots out McBurney's point." "It is wholly ununiform and useless," says Price.

If we are to receive an affirmative response to the test in obstruction, I fear the point is getting rather dull, yet it was upon this sign more than any other the erroneous diagnosis of appendicitis was made. Passing over the more common symptoms of constipation and vomiting, which were absolute and persistent in this case, the physical examination of the abdomen revealed an interesting, though not unique, condition. About the third day of the attack the attending physicians discovered a swelling in the right inguinal region, tender upon pressure and dull upon percussion. It was observed that the area of percussion dulness had increased somewhat on Saturday, the fourth day.

When I reached the patient, Sunday night, you will remember I found the entire abdomen distended. I could easily outline by percussion absolute flatness from the left inguinal region, across the lower zone of the abdomen, into the right lumbar. This swelling was tender, elastic, and fluctuant. A circumscribed enlargement in the right inguinal, developing in the wake of such symptoms as above recorded, was certainly, in itself, evidence strongly presumptive of appendicitis. The rapid increase in the size of the swelling, and the extensive area of percussion dulness, however, almost precluded that diagnosis. What, then, might it have been?

All who are familiar with abdominal tumors know that not unfrequently in their natural history they are affected by some active complication, such as torsion of the pedicle, inflammation, hemorrhage into a cyst, etc., either one of which might be attended by a rapid increase in the size of growth, and thus lead to the recognition of a tumor hitherto undiscovered.

Treves tells us that in a few exceptional cases of intestinal obstruction we may meet with a localized area of percussion dulness due to the accumulation in the captured coils of intestine.

In acute strangulation the violent peristalsis, venous engorgement, and subsequent dilatation and paralysis of the bowels above the obstruction (Senn) are all conditions highly favorable for the transudation and accumulation of fluid in the intestinal tube. It is true in a large percentage of cases of intestinal obstruction only a small knuckle or coil of bowels is imprisoned, yet for diagnostic application we should not forget in a few exceptional cases, the one here reported being a typical illustration, a loop of several feet may be incarcerated, yielding confusing physical signs.

There are two points in the pathology of this case I shall briefly allude to, viz., 1, the peritoneal false ligament or solitary band causing the strangulation; 2, the extreme distension of the strangulated loop

Upon careful investigation into Miss Sallie's previous history I am unable to learn of any disease or injury that might have given rise to a local peritonitis, yet upon the highest authority we know that this solitary band is an unmistakable evidence of previous localized peritoneal inflammation.

In the life of an individual we can easily comprehend how some slight injury or blow, some enteritis with intestinal ulceration, may have escaped the notice or memory of the family. It must also be remembered that "peritonitis may occur during intra-uterine life" (Treves). In localized peritonitis plastic effusion results in the adhesion of two opposed peritoneal surfaces.

In consequence of the ever-changing relation of the viscera, especially the rolling movements of the intestines, the band of adhesion, which at first may have been a broad attachment, is soon transformed into a cord of greater or less length. In this particular case one attachment was to the mesentery; the other to a coil of jejunum. In the arcade formed by the expanse of mesentery below, and the two inch band above, a loop of intestine slipped. No doubt at first there was quite a small coil, the accumulation and active peristalsis served to draw more through, until finally the twisting and the distension effected complete strangulation.

Reviewing the technique of the operation as performed, there are several avenues for adverse criticism. The patient, it is true, was in an extreme condition, the state of circulation and the ceaseless vomiting rendering any operative procedure hazardous. Having determined upon operation, the first step should have been copious irrigation of the stomach. The symptoms demanded this, regardless of the diagnosis. Under the influence of hot water in the stomach the pulse would have improved, the vomiting temporarily allayed, and the patient placed in altogether better condition for operation. It is with regret that I record this sin of omission; it was merely chance that it did not prove disastrous to the patient.

Incision.—Every physical sign located the trouble on the right side, hence I chose the lateral incision.

Examination.—Having determined by the condition of the cæcum that I had to deal with an obstruction in the small intestine, further intra-abdominal examination was precluded until the distended coils of intestine could be disposed of in some way.

I was given but little choice of methods. Exventration could not have been accomplished without the greatest possible risk of injury to the integrity of the bowel; therefore when I discovered a small rupture in the peritoneal coat of the most distended and presenting coil, I at once determined to evacuate by Madelung's method. The opening of the intestine was followed by such a copious and forcible evacuation of its contents, that it was not necessary to consume valuable time by the introduction of a catheter for further intestinal drainage as that surgeon recommends (Senn). I was enabled to immediately cleanse and close the intestinal wound, and, now with flaccid bowels, proceed in my search for the seat of obstruction. In this I was guided entirely by visual examination. Following up the congested coils, I soon discovered the seat of constriction. Liberating this in the manner previously described, the operation was practically complete, having disposed of the two essential indications for the relief of the intestinal obstruction, first, removal of the cause of obstruction; second, the relief of the engorged and distended bowel.

A Chicago Physician was arrested a while ago by a thick-witted policeman, who saw the doctor enter a house with his satchel, and concluded he was peddling or canvassing without license.

AN INTERESTING CASE OF SUBDURAL INTRA-CRANIAL HEMORRHAGE (WITHOUT FRACTURE) — LEPTOMENINGITIS — TREPHINING—RECOVERY.[1]

By FRED. LLOYD WELLS, M.D.,

EX-HOUSE SURGEON CHAMBERS STREET HOSPITAL, NEW YORK.

Mr. President and Gentlemen: The following is the simple history of a case brought into the Chambers Street Hospital of this city while I was acting in the capacity of house surgeon.

A good number of the cases treated in that institution present great difficulties in the way of diagnosis. They are found unconscious on the street and no clue to their identity can be obtained. Consequently the history cannot be learned, and any diagnosis made must be based entirely upon the signs present.

This patient, a German, aged about twenty-three, was suddenly seen to fall in the street. An ambulance was summoned from Chambers Street Hospital, but the surgeon upon his arrival could obtain nothing but these few facts as to the history. No one knew him. He was walking along the street, was suddenly seen to fall, and to go immediately into convulsions. These had stopped before the arrival of the ambulance, but were described as being "of his face and all his limbs." "He frothed at the mouth," "turned black in the face," and, in fact, was said to have had all the signs of a typical epileptic seizure. The contents of his pockets gave no clue as to his friends, so he was taken to hospital and immediately put to bed. An examination then made showed him to be a man of good physique, well nourished, and entirely unconscious.

He had no deformities. Tongue was bitten. We could find no evidences of any injury except a small scar on the left side of the head, anterior to and a little above the ear. This, however, was judged to be from three to six weeks old. The pupils were dilated, but equally so, and possessed reflexes. Heart and lungs were normal. Temperature, 102° F.; respiration, 30; pulse, 120. No loss of motion, and apparently none of sensation—in fact, hyperæsthesia was thought to be present. The urine was fair in quantity, and pale yellow in color; specific gravity, 1.020, and contained a slight amount of albumin, but no casts nor sugar. The bowels moved and urine was passed involuntarily. The convulsions came at intervals of one-half hour to three hours, they were clonic and general, and would last from one to two minutes. During the intervals the patient was completely unconscious and delirious, and was with difficulty kept in bed. He was given morphine sulphate, by hypodermic injection, quite frequently. Toward evening the temperature rose to 104° F. This temperature was followed by a sweat, and he became even more delirious.

The case was then seen by the acting visiting-surgeon, who advised symptomatic treatment, and careful watching in order to discover any signs which might lead to a positive diagnosis. Ice-bags were then applied to head and kept on constantly.

August 21st.—Condition remains about the same. Temperature has fallen to 103° F.; respiration, 26, and pulse, 110. The convulsions during the night were thought to be a little more frequent than during the day, but general. During the day, however, they could be more carefully watched, and were then found to begin in either the right eye, or the right corner of the mouth, to advance to the right arm and leg, and finally become general. The advance, however, was so rapid that to all ordinary observation they were general from the start. The treatment of the day before was continued. The temperature in the evening rose to 105° F., and was again followed by a sweat; the convulsions became more frequent, more severe, and even more nearly general, from the start.

[1] Read before Society of Alumni of Charity Hospital, January 6, 1892.

August 22d.—During the night the convulsions were nearly constant. The temperature in the morning was found to have become lowered to 104° F., but the patient was wasting very rapidly. He was again seen by the acting visiting-surgeon, who was unable to decide positively as to a diagnosis, but being obliged to leave town gave permission to do anything considered necessary. The patient gradually became worse, and operation was decided upon, with the idea that his trouble was due to a cerebral abscess following the old injury, the scar of which was found, and which scar was about in the location of the motor area for the face, arm, and leg of the right side. Dr. Cole, who had previously unofficially seen the case and advised operation, was then acting as visiting-surgeon, and was called, and with his assistance operation was begun. Temperature at time of operation, 105° F.; pulse, 123; respiration, 22

Operation.—All antiseptic details were carried out, the head being shaved, scrubbed, and made surgically clean. A semilunar incision, with its convexity downward, was made in such a position as to include the point of suspected compression in the concavity, and the scalp and muscles were turned up. The periosteum was found more than usually adherent beneath the scar, but was finally turned up and the bone exposed. Not the slightest evidences of fracture could be found, no elevations or depressions existed.

The trephine was applied a little above and anterior to the scar, in order to correspond more nearly with the centre of the motor area.

The disk of bone was removed with great difficulty, the dura being so adherent as to tear away pieces of the bone. The bone itself was three-sixteenths of an inch in thickness, and perhaps a little more vascular than usual, but otherwise normal. No depression of the inner table was found. The dura was dark in color and presented no pulsations

A crucial incision was made in the membrane, and a blood-clot immediately protruded. The incision was then enlarged, and a handful of clotted blood removed.

This blood-clot occupied a position immediately beneath the trephine opening, extending up along the tissue of Rolando, and covering the motor areas of face, arm, and leg of the opposite side of the body, the largest part being over the centre of the face.

Microscopical examination showed the clot to be undergoing softening and a transformation into pus. The pia was seen to be very much reddened and inflamed, the brain itself greatly compressed, but not softened.

The cavity was then cleansed with solution of bichloride, 1 to 20,000. After satisfying ourselves that no fresh bleeding was taking place the dressing was begun. A strip of iodoform gauze was introduced to the bottom of the cavity which was left by the removal of the blood-clots. A tube was introduced into the dura—but not through it. The disk of bone was not replaced. A large antiseptic dressing was applied.

The patient came from ether nicely, and during the recovery uttered the first rational words since admission by asking for a drink of water. Temperature at night (four hours after the operation) was 103° F.

August 23d.—During the night he had several convulsions general in character. The morning temperature was still 103° F. The wound was redressed, drainage being kept up by the same method.

August 24th.—No convulsions during the day, but he complained of great pain in the head. Temperature. 104° F. No convulsions during night; the patient took brandy and milk at odd times. The bowels moved and the urine was passed.

August 25th.—Had several convulsions during the night, but these were thought to be due to a slipping of the dressing and consequent pressure, as they were of the right side only and ceased when the dressing was reapplied.

It was noticed that whenever the wound was dressed a

touch of the probe upon the brain beneath the opening produced a twitching of the right upper eyelid. The patient speaks rationally, can tell his name, but has no recollection of his former life or of any accident as yet.

After the 26th the temperature fell to 99° F., and kept at about that level until his recovery. The wound was dressed once or twice a day, the discharge gradually lessening until the wound closed. He gradually regained his memory, and stated that he was struck on the head about three weeks before admission to the hospital, the scar found being the scar of that wound. It never troubled him in any way, and was thought to be of no consequence. He had had severe headaches for the last week, and for a few days before admission he had noticed that his right arm and leg were not as strong as usual, but this did not bother him sufficiently to cause him to stop work, and indeed he was working at his trade—that of a fireman—upon the day we found him.

September 2d.—The patient became irrational, but his temperature and pulse remained normal, and the wound was in good condition, so no anxiety was felt. He fully recovered from the attack in twelve hours. On September 23d the patient was discharged cured. The brain had rapidly expanded and filled the space left by removal of the blood, and the wound was entirely closed. The lack of history to aid in the diagnosis of this case adds a great deal to its interest, for if the history given upon recovery could have been obtained at the time of admission, there would have been little doubt as to the probable diagnosis. When last seen (about six months after the operation) the patient was enjoying the best of health, and not affected in any way by his previous trouble.

331 West Forty-eighth Street.

Progress of Medical Science.

Cutaneous Absorption.—The question whether medicinal agents incorporated in fatty bases are capable of penetrating the skin has been a much-discussed question, and one about which opposing views have been frequently put forth. Peters (*Centralb. für Klin. Med.*, 1890) has found that when fresh ointments were employed containing iodide of potassium, a small quantity of iodine could be detected in the urine a few hours later. Paschkis and Obermayer (*Ibid.*, 1891) experimented with oleate of lithium and a solution of the chloride, and found that exceedingly small quantities passed through the skin. Now comes the question, which of the three fatty bases usually employed most favors such absorption as may take place. According to the experiments of Guinard and Bouvet (*Revue de Thér. Méd-chir.*, November 1, 1891), if you wish an active substance to pass through the derma rendered absorbent by removal of the epidermis, you must incorporate it with vaseline, while if the intention is to secure a local action limited to the surface, axunge is the proper base. These conclusions regarding the passage of substances incorporated in fats through the intact skin are in direct opposition to the results arrived at by the observers quoted above. They are as follows: 1. The intact epidermis offers an insurmountable barrier even for substances incorporated with fats. 2. Where penetration of a medicine in pomade has seemed to be demonstrated, it has been a volatile substance which has been absorbed by the respiratory passages. 3. Perhaps exception can be made for substances susceptible of giving off vapors when applied to a fine hair-covered skin, in which case the vapors penetrate by way of the hair-follicles and gland openings, but there is no absorption by the epidermis. 4. Lanoline does not favor absorption more than axunge or vaseline. 5. On absorbing surfaces (mucous membranes and skin deprived of epiderm) vaseline gives up incorporated substances most rapidly, lanoline comes next, and axunge last.

Acromegaly.—This seems to be a rare condition, of which only some forty cases have been described. Drs. Spillman and Haushalter (*Rev. de Méd.*, September, 1891) report an instance in a nun, fifty-two years of age, in whom the disease showed itself twelve years before by tingling and loss of feeling in the fingers, followed by dulness, irritability, and gradual enlargement of the features and extremities, with much thickening of the skin, rounding of the shoulders, increase in size of mouth and tongue, etc. Loss of sight in one eye was attributed, as it has been in similar cases, to neuro-retinitis resulting from pressure upon the chiasma by the hypertrophied pituitary body, always found post mortem so far as observations go. In a second instance, reported by Dr. Cepeda (*Rev. de Ciencias med.*, January 15, 1892), the disease began in a man, at the age of thirty-five, but did not seriously inconvenience him until the age of forty-eight. Here, too, the face, hands, and feet were very large, and the tongue so increased in size as to cause much inconvenience in the mouth. The wrists and ankles were not so greatly developed as the hands and feet. There was slight glycosuria and polyuria, and anaphrodisia was noted from the first. Here, as in the preceding case, the pituitary body had attained the size of a large nut, and compressed the optic nerve, but without having changed its structure. There was hypertrophy of the great sympathetic, both in its ganglia and branches. The epiphyses of the bones of the extremities were especially increased in size.

Reproduction of the Mucous Membrane of the Uterus.—From an experimental study of this question, together with the effect of the application of Canquoin's paste (zinc chloride) in the uterine cavity, Dr. Bossi draws the following conclusions (*Nouv. Arch. d'Obst. et de Gynéc.*, December, 1891): 1. The mucous membrane of the uterine body in the bitch, abraded by free cuts of the bistoury extending through its whole thickness, is reproduced in its integrity, that is to say, with the formation of true glands. 2. Reproduction takes place slowly, and sometimes, by reason of conditions not well determined, is subject to considerable retardation. 3. The covering epithelium, which primarily extends over the wounded surface, derives its small glands from the borders of the cut. 4. The newly formed glandules derive from the proliferation of cells a new covering epithelium when it has acquired the cylindrical form.

Vibratory Massage of the Nose.—Dr. Pierce (*The Journal*, October 10, 1891) reviews Dr. Braun's paper and relates six cases of his own, treated by the new method. Copper sounds, covered with cotton and suitably medicated, are introduced into the nostrils and made to vibrate from two hundred to three hundred times per minute, reaching in succession all parts of the nasal cavity. The originator had treated one thousand cases, and found the most striking results in fetid atrophic rhinitis, the atrophied turbinated bodies returning to their normal proportions. The conclusions reached by Dr. Pierce are: 1. To the cleanliness which is made so essential in this mode of treatment are due most of the speedy cures or relief of disagreeable symptoms, *i.e.*, fetor, secretion, etc. 2. The vibratory movements themselves may be indeed of some benefit, inasmuch as they are stimulating to the lymphatics and vascular system, but they have little or no action in regenerating atrophic tissue.

Diabetes from Removal of the Pancreas.—Dr. Lancereaux (*Bul. de l'Acad. de Méd.*, September 29, 1891) presented a dog, rendered diabetic in his laboratory, thirty-five days before, by the almost complete ablation of the pancreas, and now showing the features of pancreatic diabetes, having reached the period of marasmus. The study of the case shows that pancreatic section, with ablation of the vertical portion of the organ, produces an azoturic diabetes with phenomena of profound denutrition, soon followed by a return to perfect health. Almost complete ablation brings about in full the whole symp-

tomatology of diabetes with loss of flesh, and, while the diabetes has been intermittent, it has been unceasing in its progression. Total destruction of the pancreas, *in situ*, does not cause diabetes, while section, ablation of the normal gland, or suppressing its function always produces it. Lancereaux was the first, some eleven years ago, to demonstrate the existence of pancreatic diabetes, but like the experimental glycosuria of Claude Bernard, produced by injury of the fourth ventricle, it has not been of such value to man as had been hoped for.

Duboisin in Insanity.—Dr. L. Lewald (*Neurol. Centralb.*, October, 1891) has treated twenty-two cases of various forms of insanity with hypodermic injections of sulphate of duboisin in doses of $\frac{1}{3\frac{1}{2}}$ grain and less. The effect is more marked in women than in men. Mydriasis is an early symptom. In three-quarters of the cases sleep, varying from two to seven hours, was secured, while in twenty-four per cent. a persistent state of tranquillity without sleep followed.

Revaccination.—In discussing the period of life at which revaccination should be practised, Dr. Hervieux (*Bul. de l'Acad. de Méa.*, February 2, 1892) concludes a paper as follows: 1. Revaccinations should be made, the first at ten years, the second at twenty, and revaccinations *en masse* in regions which are threatened or invaded by severe epidemic of variola. 2. No one should plead an exception to the rules of the civil or military authorities because of cicatrices of vaccination or of variola more or less marked.

Hydrocele in the Female.—A woman, aged forty-five, was admitted to the clinic presenting in the region of the labium major, and extending toward the external inguinal orifice, a good-sized tumor of elastic consistence, pseudo-fluctuating, painless, and not reducible into the abdominal cavity. It had appeared a year before without appreciable cause. An incision was made in the long axis of the tumor, which opened into a closed cavity filled with a yellow fluid. In the interior of the cavity, and floating in this fluid, was a small elongated sac, thin and transparent, filled with colorless liquid and adherent to the superior angle of the hydrocele cavity. This was evidently an old hernial sac transformed into a cyst. It was excised, the hydrocele cavity closed by suture, and the external wound closed over it. A complete cure resulted.—*Annales de la Soc. Méd.-Chir. de Liége*, December, 1891.

Some Affections of the Rectum.—The procedure which Verneuil has proposed for the cure of prolapse of the rectum has for its object the attachment of the prolapsed bowel to the region of the coccyx. The steps to be followed in operating are thus given in the *Boston Medical and Surgical Journal*, October 8, 1891: "After reposition of the prolapsed portion, with the patient in the lithotomy position, two incisions, from four to five centimetres in length, are made, at right angles to the long axis of the anus, from the opening of the latter, in an outward direction. From the point where these incisions terminate, two other incisions pass to meet each other at the point of the coccyx, thus including an equilateral triangle with its base placed anteriorly. This triangular flap is loosened from behind forward, and left temporarily attached to the tissues surrounding the anus, comprehending in its thickness the skin, the subcutaneous cellular tissue, together with the fibres of the external sphincter. With this flap strongly retracted by means of blunt retractors, the posterior wall of the rectum is loosened for a breadth of from five to six centimetres, and to a height corresponding to the distance from the anus to the tip of the coccyx. Four threads are now passed transversely through the posterior rectal wall, parallel with each other, and not including the rectal mucous membrane. The upper one of these sutures is placed at a point in close relation to the point of the coccyx, while the lower one is removed about fifteen centimetres from the anus. By means of a needle with an eye at the point, which is passed through the skin from without, the threads are drawn through the points of emergence of their respective ends, being selected at about four centimetres from the median lines at either side. The upper suture should be on a level with the articulation between the first bone of the coccyx and the sacrum, and the lower at about the point of the coccyx; the intervening sutures are placed about equidistant between. These are now secured upon one side in such a manner that the first and second, and the third and fourth are tied together, rolls of iodoform gauze being placed beneath the loops to prevent the latter from being buried with the skin; strong traction upon these secures the rectum in its new position, and the other ends of the thread are similarly secured. The triangular-shaped flap is now removed, the muco-cutaneous anal margin being preserved, and after inserting a drainage-tube the wound is closed by sutures."

In complete prolapse of the rectum Dr. Cripps (*Lancet*, No. 15, 1890) says that while complete excision is occasionally necessary, the lineal cautery, by producing an inflammatory exudate in the submucous tissue, cements the coats together and prevents the slipping of one coat upon another, and hence the prolapse. The actual cautery is preferred, and four lines are drawn from the apex of the protrusion to the margin of the anus, each a quarter of an inch wide and sufficiently deep to sear, but not to destroy, the mucous coat. In a lecture on common diseases of the rectum (the *Canada Lancet*, February, 1892) Christopher Heath says a little painful swelling caused by a bluish mass by the side of the anus, more common in men than in women, is due to a thrombus in one of the inferior hæmorrhoidal veins, the result of constipation, overloaded liver, and obstructed venous circulation. This may get well by absorption of the blood-clot and leave behind a loose fold of skin, commonly known as loose external piles. The best treatment is to make a nick with a bistoury, and turn out the clot. In ischio-rectal abscess, from whatever cause, the sooner you make an opening the better. If the rectal wall is thinned from encroachment, it is better to open at once into the rectum to avoid fistula formation. Hemorrhage from the rectum depends in the majority of cases on internal piles, but a vascular patch of mucous membrane in the rectum may be the cause. These are the only cases of rectal disease which do well under caustic, and here the strongest fuming nitric acid, or, as he prefers, acid nitrate of mercury can be used, locking up the bowels with opium for a day or two. Gonorrhœa of the rectum has been seriously questioned by many observers, but Dr. Tuttle believes the discovery of the gonococcus has put at rest all contention upon this point. He reports three cases seen during the past two years (*New York Medical Journal*, April 2, 1892), which are interesting because of the few reported cases verified as those were by examination for the bacillus. Dr. Kelsey (*New York Medical Journal*, March 26, 1892) considers the carbolic acid injection of hæmorrhoids one of the most uncertain plans of treatment. Exceptional cases, in which sloughing or gangrene took place, followed by protracted healing, etc., have led him to abandon it. Operations with the clamp and cautery give the most satisfactory results.

Accumulation of Bromide of Potassium in the Tissues.—M. Féré, in some experiments on the accumulation of bromide of potassium in the body, has found that all the tissues tend to retain the salt; those, however, of which the nutrition is slow, such as cartilage and bone, retain it longest, and the amount held in the different tissues is very varied. This result is comparable with that obtained by Richet for chloride of lithium; it appeared to him that the kidney had the greatest affinity for this latter salt.—*British Medical Journal.*

Salol.—It is now almost ten years since Nencki discovered salol, and although it has been employed therapeu-

tically only since 1886, it may be said to be constantly gaining favor and having its range of usefulness increased, both as an internal remedy and as a local disinfectant. Dr. Egasse (*Bul. Gén. de Thér.*, September 30, 1891) shows how, from its early use in rheumatism, because of its analgesic and antipyretic properties, it has been gradually adopted in the treatment of such diversified affections as urticaria, diabetes, intestinal catarrh, typhoid fever, cholera, catarrh of the bladder, migraine, sciatica, diarrhœa, gonorrhœa, gonorrhœal rheumatism, yellow fever, throat affections, pneumonia, pleuritis—to say nothing of the many local conditions in which, as an external application, it has been found invaluable. Chéron (*Journal de Méd.*, September 20, 1891) says that to be sure of absorption, it must be administered about three hours after meals, at the time when the pancreatic secretion is the most active. He advises the combination with pancreatine, salol in powder, 10 grammes; pancreatine, 2 grammes. Make twenty powders and give two three hours after each meal. In catarrh of the bladder in women, from a variety of causes, salol brings about a rapid cure if the catarrh is not of too long standing. Local applications are sometimes followed by erythema, which disappears when the salol is discontinued.

Three Varieties of Favus.—Dr. Unna reaches the conclusion, after investigation of the subject (*Fortsch. der Med.*, No. 2, 1892), that three kinds of favus exist, and he has named them griseus, sulfureus tardus, and sulfureus celerior. The fungus corresponding to each of these varieties is called achorion euthythrix, achorion dickroon, and achorion atakton. Experiments were made with mice, rabbits, and upon the experimenters themselves; and in a colored plate is seen depicted, side by side, the scutula of the griseus and sulfureus celerior varieties as they appear upon the human skin. The sulfureus tardus is shown on the head of a mouse. It has been observed that when a mouse is affected with favus he is eaten by his fellows, and the author thinks the spread of the disease is accounted for in this way. Two of the varieties have been observed upon mice in the free state. Drs. Frank, Williams, Roberts, and Douglas assisted in the investigations.

Transmissibility of Cancer.—Drs. Duplay and Cazin (*La Méd. moderne*, February 25, 1891) have communicated to the Academy of Science the results of their experiments in inoculating cancer, from which it appears that all attempts, both as regards the transfer from man to animals and from one animal to another, have failed, and they think it demonstrated that transmission does not occur. It is, however, regarded as premature by the authors to state definite conclusions respecting the transmissibility of cancer from one animal to another of the same species.

Irrigation without Catheter in Posterior Urethritis.—In order to escape the irritation which accompanies catheterization Dr. Rona (*Memorabilien*, January, 1892) employs an irrigator furnished with a hard-rubber nozzle to wash out the whole urethra in urethritis gonorrhoica totalis. With a syringe it is very difficult to throw fluid into the bladder, while with an irrigator, placed at the height of one and a half meter, the compressor is overcome, as a rule, in from a few seconds to a minute, especially if the patient's attention is distracted by conversation. The quantity of medicated liquid to be introduced is about a hundred to a hundred and fifty grammes.

Diffuse Hypertrophy of Breasts.—Dr. Porter (*Boston Medical and Surgical Journal*, No. 9, 1892) operated within an interval of three weeks on both breasts in a case of diffuse fibroma with tendency to intracanalicular growth, removing the smaller breast first, which weighed seventeen pounds, and the larger afterward, which weighed forty-three. A hard lump had made its appearance three years before, when the woman was thirty four years of age. At the time of removal the largest circumference was thirty-eight inches. The bulk of the growth was made up of fibrous tissue rich in cells and holding in the interstices considerable thin, serous fluid. The operation was successful, as it has usually been in the nineteen cases found in the literature of the subject.
